If there was one more important feature than the rapidity of the outbreak, it was that the epidemic faded away—for that is the only term that can be applied—so abruptly. Numerous explanations have been put forward to account for this, but the only factor that appears to have had any real determining influence in bringing about this abrupt cessation of the disease, was the universal adoption of re-vaccination after small-pox had already obtained its firm foothold in the city.

That Dr. Coupland is not going beyond his brief when he holds that this high child mortality was due to the unvaccinated condition of many of the children, is evident from certain statistics which he gives concerning 3546 cases. Of these only 85, or 2·5 per cent., were in vaccinated children below the age of ten years; and amongst these 85 cases there was only a single death.

These were all cases recorded in papers and reports which had come directly under Dr. Coupland's personal observation during his investigations into the outbreaks of small-pox in Dewsbury, Manchester, Oldham, Leeds, Halifax, Bradford and Leicester. In the Dewsbury, Leicester, and Gloucester outbreaks the number of children that had not been vaccinated was very high indeed. Now, taking Dewsbury, where the proportion was lowest, the number of deaths to attacks was as one to nine; in Leicester, as one to seventeen; and in Gloucester—where the proportion of unvaccinated was highest of all—the proportion of deaths to attacks was as one to four and a half, although the attacks in Gloucester were nearly 2000 (1979), in Leicester 357, and in Dewsbury 1029.

Comparing these three outbreaks, and bearing in mind the proportion of unvaccinated as above, we find that the proportion of the whole number attacked under ten years was in Dewsbury 21·7 per cent., in Leicester 30·5 per cent., and in Gloucester 35·6 per cent.; the fatality of this class in the three cases being Dewsbury 25·4 per cent., Leicester 13·7 per cent., and Gloucester 39·6 per cent.

As affording evidence of the disproportionate incidence of the disease upon young children, to which reference has already been made, it may be stated that 706 of the whole number attacked, or 35·7 per cent., were under ten years of age; whilst of the 434 fatal cases 280, or 64·5 per cent., occurred in this age period. Of these 706 only 26 had been vaccinated before the epidemic broke out, whilst of the remainder, 80 were undergoing vaccination when attacked with small-pox, the operation having been performed within fourteen days of the onset of the disease. It will thus be seen that only 4 per cent. of those attacked at this age period had been vaccinated, although a much larger proportion of vaccinated had been exposed to infection. It is found that of those exposed to infection, in households invaded by small-pox, of the vaccinated class 3386, and of the unvaccinated class 1475, there were attacked with small-pox—of the vaccinated class 1028, or 30·3 per cent.; whilst of the unvaccinated class 689, or 46·6 per cent., became infected.

It has already been indicated that amongst the unvaccinated at Gloucester the type of the disease was much more severe than in the vaccinated class. For purposes of comparison it may be shown that in Gloucester, where, as we have already seen, the number of unvaccinated children was very high—much higher than in Dewsbury or Leicester—the type of the disease over all was much more severe than at either Dewsbury or Leicester, and still more so than in many of the other recent outbreaks. Taking the severe type as including malignant and confluent cases, and the milder type as including coherent, discrete and mild cases, we find that in Dewsbury 26·5 per cent. of all attacks were of a more severe type, in Leicester 26·8 per cent., and in Gloucester 43·1 per cent.; whilst the mild type accounted for 27·5 per cent. in Dewsbury, 35·5 in Leicester, and only 25·5 in Gloucester.

If we now take out Dr. Coupland's figures as regards attacks of small-pox affecting vaccinated and unvaccinated patients, we find that in Dewsbury 64·3 per cent. of the whole number, with a mortality of 2·7 per cent., were vaccinated; in Leicester 55·8 per cent., with a mortality of 1 per cent.; in Gloucester 61·2 per cent., with a mortality of 9·8 per cent. These figures compare very favourably with the cases of deaths in the unvaccinated class. There were 35·7 per cent. of the whole cases that had not been vaccinated in the Dewsbury Union, and amongst these there was a fatality of 25 per cent.; in Leicester 44·3 per cent. of the cases were unvaccinated, with a death-rate of 12 per cent; whilst in Gloucester 38·8 per cent. of the cases had not been vaccinated, and amongst these there was a death-rate of 40·8 per cent. It will thus be seen that the lowest death-rate in the unvaccinated class (12 per cent. at Leicester) was considerably higher than the highest death-rate in the vaccinated class (Gloucester, 9·8 per cent). It must be borne in mind, of course, that even in the worst vaccinated districts the proportion of unvaccinated to vaccinated persons is very much lower than the proportion of vaccinated small-pox cases to non-vaccinated cases, so that we not only have an enormously greater mortality amongst those attacked, but the percentage of attacks is also considerably higher.

Any one who goes carefully and with unbiassed mind into the statistics collected by Dr. Coupland must inevitably come to the conclusion that, although the disease was spread in schools owing to the simultaneous infection of school children from cases unrecognised by, or unknown to, the authorities until the area of infection had been considerably widened; although after the sudden outbreak of small-pox it became, first, a difficult—and eventually an impossible—task to isolate the patients attacked, and to treat even a small proportion in hospital; and although insanitary surroundings and a certain amount of overcrowding may have played some part in spreading the disease, we must ultimately fall back upon the neglect of a large number of parents to see to the vaccination of their children for an adequate explanation of the extent of the epidemic and the rapidity of its extension. The utter futility of all ordinary measures recommended for the limitation of the spread of small-pox, apart from vaccination, is only too clearly brought out.

Hospital accommodation and isolation are usually insisted upon, by those who do not believe in vaccination, as being sufficient to prevent any outbreak of small-pox assuming serious epidemic proportions. Now, what did Dr. Coupland find at Gloucester? That a few slight or mild cases in 1895 were followed by a severe epidemic extending from February to April 1896, in which not only was there an increase in the numbers attacked, but there was also an undue proportion of cases of a severe type accompanied by a high rate of mortality. As showing how in a community with a large proportion of unvaccinated children the disease may spread rapidly, we have the fact that there was an "almost simultaneous invasion of many homes through children who were infected whilst attending certain of the public elementary schools." As a result of this sudden outbreak it became impossible to provide hospital accommodation, and, ultimately, all attempts at isolation, of even a modified form, had to be abandoned as utterly impracticable. As a result of the crowding of the hospitals, and of the removal of the most severe cases to them, the hospital mortality was comparatively high, and the friends of the patients would soon not permit of the removal of these patients to hospitals; this, of course, resulting in an utter break-down of the system of isolation.

Dr. Coupland sums up in the following exceedingly striking passages. He says: "There is no escape from the conclusion that the heightened mortality and the severity of the epidemic were greatly due to so large a proportion of unvaccinated children being attacked; for (*a*) the case mortality under ten years of age was 39·6 per cent., whilst amongst the vaccinated it was only 3·9 per cent., leaving a mortality amongst the unvaccinated of 41 per cent. . . . (*b*) The disparity is quite as marked when the type of the attack is contrasted, for of 507 cases of *severe* attacks [malignant, confluent, indeterminate] there actually occur only three amongst the vaccinated." From these and other considerations it follows that in the Gloucester epidemic "the severity of the disease, its high mortality, and its propagation were influenced and promoted by the unduly large proportion of unvaccinated children who were exposed to infection and who were infected."

To whatever figures or tables we turn, the effect of them is always the same. They tell the same story — vaccination protects; unvaccinated children are left susceptible to the attacks of the disease, and they not only take the disease more readily, but they take it in a more dangerous and fatal form, and, in most cases at any rate, are a source of greater danger to those with whom they may come, directly or indirectly, in contact. Isolation, good hospital accommodation, and favourable sanitary conditions are useful in the treatment of small-pox in a vaccinated community; but once let small-pox find its way into an unvaccinated community, the inefficiency of these "accessory" measures, when used alone, are demonstrated with the most absolute clearness; and if Gloucester has one lesson more than another to teach, it is that Jenner, by his advocacy of vaccination, did more to limit the spread of small-pox than have all the sanitarians of the century. Small-pox undoubtedly does not come under the class of diseases that can be held in check by ordinary sanitary measures; these, no doubt, are contributory, but without vaccination they can never be depended upon as being fully effective.

CANADIAN GEOGRAPHY.

THE reissue of "Stanford's Compendium" now includes Australia and the Pacific Islands in two volumes by separate authors, Asia in two volumes and Africa in two volumes by the same author, and vol. i. of North America.[1] The new issue is in many ways vastly superior to the old; the cramping influence of the foreign original has disappeared, the illustrations have greatly improved, and, linked by the general title, each of the volumes forms a separate and original work of distinct value. So good, indeed, has "Stanford's Compendium" become, that it may now be allowable to subject one of its volumes to criticism of a more searching kind than would have been justified formerly. Then any attempt to form a library of solid geographical works in the English language was worthy of commendation; now it is possible to set up a higher standard, and it is reasonable to look for those excellencies of grasp and arrangement which one naturally expects in, let us say, a German work of similar scope.

The morphological unity of the continent is one of the fundamental facts of modern geography. The continent is the natural unit which must be considered in its entirety, with parts subordinated to the whole, and with functional activities of a distinctive kind. It is capable of subdivision, either naturally into regions or artificially into countries, and of aggregation with other continents to form the whole land-surface. The dominant lines of the continent—its axial mountain systems—determine the primitive slopes of the land, and the development of the river systems, subject to the continuous workings of secular uplift or depression and the accumulation of sediment. The resulting configuration modifies the climate as dependent on latitude, and leads to the formation of areas of moderate and of extreme temperature, of high rainfall and of aridity. Climate reacts on vegetation, and vegetation and climate together influence the distribution of animals; and all these varieties of feature and function are framed in the continent. Thus up to the appearance of man a geographical description must be based on the continent as a unit if it is to be really simple and comprehensible. With the advent of man complications arise, but the guiding influence of the main features of continental relief and surface-covering is still to be traced. The deep inlets tempt the adventurous stranger to penetrate the continent, the easy waterways lure him into the interior, where products of forest and plain supply an adequate inducement to remain or to return. In time groups of people settle down in habitats more or less distinctly defined by natural features—different tribes frequent the river, the lake, the forest, the plain, the mountain valley, the indented ocean shore.

[1] "Stanford's Compendium of Geography and Travel" (new issue). North America. By S. E. Dawson. Vol. i. Canada and Newfoundland. Maps and illustrations. (London: Edward Stanford, 1897.)

Consequent pressure of population or change in the availability of resources sets up migratory movements along natural lines dictated by land-form, water-flow, and soil-covering; conquest and delimitation ensue, and the straight boundary lines of the map, which come last, are, after all, natural relations to geographical facts associated with the whole body of the earth itself and its rotation. The grouping of dwelling-places around certain centres leading to the origin of towns may also, as a rule, be explained by geographical considerations.

Of the six continents which are usually recognised two stand out from the rest, distinguished by the simplicity of their great features and the clearness of the interdependence of the various relationships. These are North and South America, either of which forms an ideal subject for a geographical monograph.

We have mentioned the superiority of the new issue of "Stanford's Compendium" over the old; but there is one point of distinct inferiority. The old issue retained some traces of the original design, giving it a certain unity; the new is not so much a compendium as a series of separate works. Dr. S. E. Dawson's "North America, Vol. i.," is not, strictly speaking, the first part of a geographical description of North America. It is the description of the Dominion of Canada and Newfoundland, written not from the standpoint of a geographer, but from that of an imperialist British subject and patriotic Canadian. The author infuses warm colour into his narrative, which, gratifying as it must be to the sentiments of the people of the British Empire, does not enhance the value of the work as a scientific treatise. Dr. S. E. Dawson is obviously not himself a geographer—his strength lies in his treatment of history. Having expressed our view as to what a geographical treatise on a continent should be, we need only add that "North America, Vol. i.," is written without regard to the guiding principles of geographical science.

We have seldom, if ever, read more satisfying or more graceful renderings of history than the chapters of this book dealing with the discovery, exploration and occupying of the provinces of the Dominion. Unexpected comparisons and contrasts of the aptest kind with the course of history in other lands and other times continually delight the reader's mind and illuminate the story. But when from history the author enters geography the wheels seem to drop from his chariot, and he drives heavily. One could imagine that he wrote with effort, perhaps even with distaste. His comparisons lose point, and are sometimes inaccurate. Canada is not, as stated on p. 29, "above all others the land of abundance of waters." Finland or Sweden would, we believe, correspond better—certainly as well—to the definition. If any great river is to be celebrated for the length of its tributaries it should surely be the Amazon, the Congo, the Mississippi, rather than the St. Lawrence (p. 34). As to climate, we dispute the suggestion that tobacco cannot be grown in England (p. 47), and we must remember the success of Lord Bute's wine-making from grapes grown in the open air at Cardiff. The treatment of climate is otherwise not fully satisfactory. While no attempt is made to deny that the Canadian winter is cold, the author seems more concerned to combat what he believes to be the average Englishman's exaggerated ideas on the subject than to describe the actual conditions. With regard to the French of Quebec (p. 295), which some people seem to have called a *patois*, the author observes: "English is not spoken in the same way over all the United Kingdom, but no one speaks of a Dublin or an Aberdeen *patois*, or for that matter of a London *patois*." We can assure him that some people do speak of the *dialect* (a word as displeasing as *patois*) of these parts, and many authors, with an eye to popularity, delight to exaggerate rather than minimise such differences. The tunnel at Sarnia, 6025 feet long (p. 391), cannot be termed "one of the greatest in the world," unless the standard of greatness is put very low, and the number of great tunnels made very large.

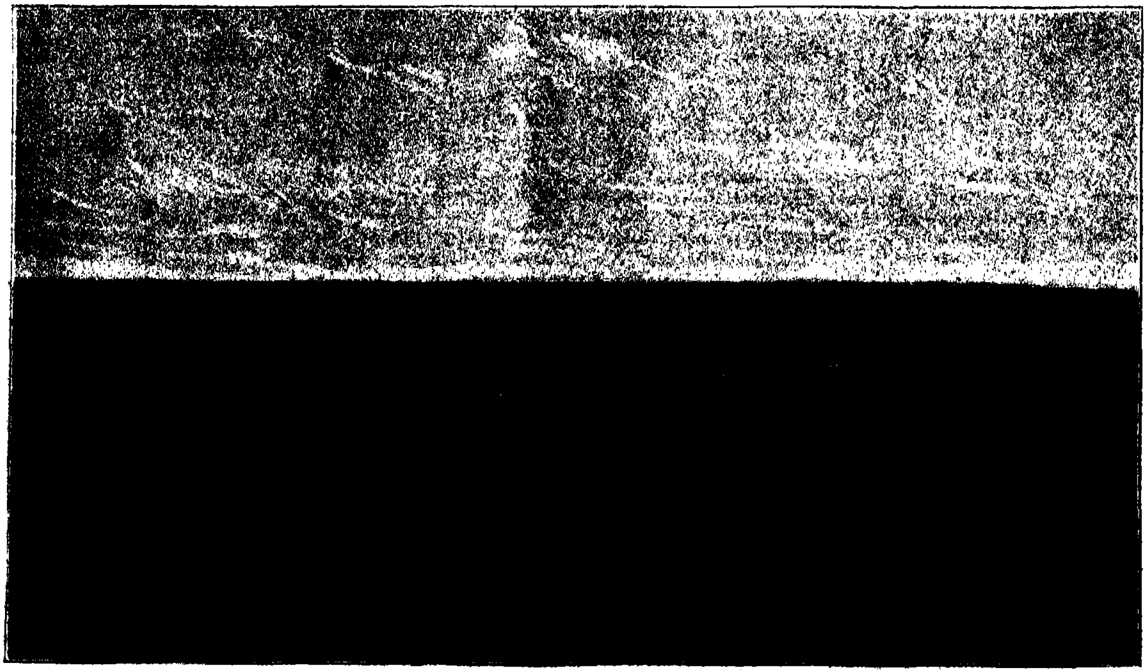

FIG. 2.—The Prairie, Manitoba.

These are instances which do not seriously detract from the value of the book to the general reader; but Canada is so great, and its natural resources are so vast, that comparisons of the kind would be quite unnecessary even if they were sound. A somewhat serious defect is the occasional imperfect revision, giving rise in the non-historical sections to repetition and to vague or even inaccurate phrases, such as the description of a boundary as a "perpendicular line" (p. 453) when a meridian is meant. We note a few omissions: nothing appears to be said of the extreme danger of the Magdalen Islands, in the Gulf of St. Lawrence, to shipping; of the devastation of the forests in many parts of the country by fire; or of the high "benches" or river-terraces of British Columbia, which to a geographer form, perhaps, the most striking feature of that wonderful province.

We must, however, make it perfectly distinct that so far as the matter in this book is concerned the omissions are trifling, and the selection of facts most judicious. Dr. S. E. Dawson handles themes regarding which a Canadian might justly be excused if he were to indulge in a little exaggeration; and if the writer of this notice had never seen Canada, he would have supposed that there was some exaggeration here. But a journey from Quebec to Nanaimo, with visits to various points in the Kootenay and on the shores of the Great Lakes, has convinced the critic that in every estimate of natural wealth, and in every appreciation of the law-abiding enterprise of the Canadian people, the author has under-stated rather than over-stated the facts. If a passing tourist of no very imperialistic tendencies felt the pride of a citizen of the British Empire rising within him with each mile of the magnificent railway which is the benefactor of every province in the Dominion, he cannot but be surprised at the moderation of tone adopted by an heir of that fair heritage in writing an account of its actual and potential greatness.

Yet the book is not planned in harmony with the principles of geography, and that, after all, is the aspect to which attention must be called in the pages of a scientific journal. The illustrations are good, and characteristic, as the specimens here reproduced show, and the maps very fair, although not so numerous or so well selected as we could wish. There are practically no physical maps, for the sketch of the Archæan nucleus on p. 24 is a mere diagram, and the "Meteorological Map" shows only mean annual isotherms, which give no clue to the climate, and rainfall areas, which are difficult to grasp as a whole. There is certainly no lack of cartographic material in Ottawa, as the beautiful physical maps in the "Handbook of Canada," issued in connection with the recent meeting of the British Association, prove. HUGH ROBERT MILL.

THOMAS JEFFERY PARKER, F.R.S.

THOMAS JEFFERY PARKER, whose death on November 7 last we chronicled on December 23, was the eldest son of the late William Kitchen Parker, F.R.S., the world-renowned comparative osteologist. He was born at 124 Tachbrook Street, London, S.W., on October 17, 1850, and received his elementary education at Clarendon House School in the Kennington Road, under Dr. C. H. Pinches. In 1868 he entered the Royal School of Mines as a student, taking the Associateship in Geology in 1871, together with the Edward Forbes medal and prize of books for distinction in biology. Thus qualified, he became for a short period science master at Bramham College, Yorkshire; but in 1872, on a special invitation by Huxley, he returned to London to fill the office of demonstrator under him at South Kensington, and that he held until his appointment in 1880 to the chair of Biology in the University of Otago, Dunedin, N.Z. During his period of demonstratorship he also held the office of Lecturer in Biology in Bedford College, London, and officiated as examiner in Zoology and Botany to the University of Aberdeen and as an assistant examiner in Physiology to the Science and Art Department. Parker was of a distinctly artistic temperament, æsthetic, musical, well-read, and possessed of marked literary ability, which asserted itself to a conspicuous degree in his little book upon his father, published in 1893, an altogether ideal filial biography—a good work by a good man. He early cultivated the critical faculty, as a direct result of the study of Matthew Arnold, whose writings he knew by heart; and with the great power of application and strength of character which he displayed during active work, there can be little doubt that he would have succeeded in any of the higher walks of life. He would have made a mark in literature, and as a caricaturist draughtsman would have achieved renown; and there is little doubt that his choice of biology for his life's calling was largely due to the charm and influence of his father's career and to his early association with Huxley, who knew him from childhood and became the object of his veneration. Both as a teacher and investigator Parker was untiring and thoroughly trustworthy. Though easily roused to enthusiasm he rarely became excited, and his cool deliberation came welcomely to the aid of the troubled student, to whom if in earnest his attention knew no bounds. His published papers exceed forty in number, and though mostly zoological they embody important work and observations in botany. Parker was the first appointed of the little band of biological professors sent out from home in the '80's, who now fill the Australian and Novozelandian chairs, and his second paper published in New Zealand dealt with a new species of Holothurian (*Chirodota Dunediensis*), as it were in anticipation of the later determination by himself and his contemporaries at the Antipodes to devote their attention to the indigenous fauna, rather than to refinements in histology and the like which could be better studied at home. The work already achieved by this body of investigators, with Parker at their head, is now monumental, and none of it more so than Parker's monographs "On the Structure and Development of Apteryx" and "On the Cranial Osteology, Classification, and Phylogeny of the Dinornithidæ," in themselves sufficient to have established his reputation. His lesser writings, although they deal with a wide range of subjects, show interesting signs of continuity of ideas, as for example in the association of his early observations on the stridulating organ of *Palinurus*, made in London in 1878, with those upon the structure of the head in certain species of the genus (one of the most charming of his shorter papers), made on the voyage to New Zealand, and upon the myology of *P. Edwardsii*, which, in co-operation with his pupil Miss Josephine Gordon Rich (now Mrs. W. A. Haswell), he in 1893 contributed to the Macleay Memorial volume. And the same may be said of his work on the blood-vascular system of the Plagiostomi. Soon after his arrival at the Antipodes, Parker instituted a series of "Studies in Biology for New Zealand Students," and chiefly with the aid of his pupils, these have been continued, either in their original form or in that of theses for the higher degrees of the University of New Zealand, as contributions to the publications of the Museum and Geological Survey Department of that colony. Botanical as well as zoological topics were thus taken in hand, the series, like that of a companion set of "Notes from the Otago University Museum," which he from time to time contributed to the pages of NATURE, containing important observations of general biological interest. Of Parker's books, it is sufficient to recall his "Lessons in Elementary Biology," now in its third edition and recently translated into German, undoubtedly the most important and trustworthy work for the elementary student which has appeared since Huxley and Martin's epoch-marking "Practical Instruction in Elementary Biology," published in 1875. Parker's book, in sharp contrast to his previous "Zootomy," which is a severely didactic and somewhat uneven laboratory treatise, is a book for the study, beautifully balanced and poetic in idea. It has a charm peculiarly its own, and to ponder over it is to appreciate to the full the honest, loving, sympathetic temperament of its author, and the conviction which he was prone to express that in the progress of scientific education there lies the panacea for most human ills, mental and corporeal. Great though the merits of these books, Parker five years ago essayed a more formidable task, in the resolve to prepare in conjunction with his friend Prof. W. A. Haswell, F.R.S., of the Sydney University, a general text-book of zoology. This work of 1400 pages, in two volumes, as recently announced in NATURE, will be noteworthy for the large number and excellence of its original illustrations; and from a passing knowledge of its contents, I am of opinion that it will do much towards relieving English text-book writers of the opprobrium begotten of a too frequent content with mere translation and continental methods. And when we consider that Parker was not spared to see this great work in circulation, it is heartrending to relate that, though ailing and weak, he had since arranged with his co-author and publishers for the production of a shorter text-book to be based upon it, and had prepared the preliminary pages of yet another elementary treatise to have been entitled "Biology for Beginners," while as a next subject of research he had begun to work out, in conjunction with Mr. J. P. Hill, Demonstrator of Biology in the Sydney University, a series of Emeu chicks, including those collected by Prof. R. Semon during his expedition into the Australian Bush. The thoroughness of Parker's best work was its most distinctive character, and when tempted to generalise he always did so with extreme caution and consideration for others, fairly presenting all sides of an argument. As he remarked of himself with characteristic modesty, in a letter written in 1894 commenting upon his chances of securing a chair of Zoology at home then vacant, "I don't profess to be brilliant, but I am vain enough to think that I have the gift of exposition and can do a straightforward research so long as it does not involve anything about the inheritance of acquired characters." Far-reaching generalisation and random rhetoric had no charm for him, nor was he tempted into over-ambition and haste so oft productive of slip-shod and ill-conditioned results. As a writer and lecturer he was always logical, cautious, temperate, content could he but spread, extend, and help systematise our knowledge of observed facts, convinced that if this be done properly their ultimate teachings become self-evident. His work is of that order which marks the growth of real knowledge and the consequent bettering of mankind; and the thought that there has thus early passed from the ranks one so good and earnest, so well fitted by nature for the responsible task of training the young and susceptible, fills us with sorrow.

Parker matriculated at the London University in June 1868, and passed the Intermediate Science Examination in 1877 and the final B.Sc. in 1878, while the D.Sc. was but a matter of formal application *in absentia* in 1892. He was in 1888 elected a Fellow of the Royal Society, and in 1880 an Associate of the Linnean Society of London, resigning the Associateship for the Fellowship of the latter but a short time before his death. He was an active member of the New Zealand Institute, to which he communicated several papers, and he became in turn Secretary and President of its Otago branch. Before these bodies and elsewhere in New Zealand he delivered addresses which will linger in the memory of his hearers and those who have read them. There may be especially mentioned an address delivered before the Otago University Debating Society on September 17, 1892, upon "the weak point in our university system," in reality an eloquent appeal for post-graduate study. Proceeding to classify an average assemblage of students into "the able, the mediocre, and the stupid," he remarked that "the only duty of members of the university towards the third class appeared to be that of imposing a sufficiently severe entrance examination to keep them from wasting their own time and their parents' money, in the vain attempt to train to purely intellectual pursuits an organism which nature intended to make its way by virtue of muscle and mother wit." A more ingenious defence of an examination system could hardly be imagined. It is preceded by the shrewd remark that "the republic of science and letters is an aristocratic, not a democratic republic." Parker was evidently of opinion that what the world terms breeding and feeding count for a great deal in the end, and the whole context of his address is apposite to the share he took in the work of organisation of the University of New Zealand, which led at least to a humanising of its syllabus in biology. And for any one desirous of a knowledge of Parker at his best in a popular function, a speech delivered on the occasion of the prize-giving at the Otago Boys High School on December 13, 1894, may be recommended, as a perfect example of the kind of thing appropriate to such an occasion, so oft provocative of the mere "airy nothing." Parker was, further, a Corresponding Member of the Zoological Society of London and of the Linnean Society of New South Wales, a Member of the Imperial Society of Naturalists of Moscow, and we believe he was President-elect of the Biological Section of the Australasian Association for the Advancement of Science for the present year. He was also a Fellow of the Royal Microscopical Society; and, ever ready to help in a good work, he became one of the original assistant editors who, under the generous leadership of Frank Crisp, in 1879 elevated the Society's Journal to its present important status.

The key-note of Parker's life-work is his connection with Huxley, and in testimony to his devotion to his great chief ("the General," as he loved to call him) there remains the delightful dedication of his "Lessons in Elementary Biology." Parker entered Huxley's service as Demonstrator in Biology at South Kensington in 1872, immediately after the conclusion of the memorable course of instruction there given, now historical as having marked the introduction of rational methods into the teaching of natural science. In the conduct of that course Huxley, as is well known, secured the aid of leading British biologists of the time. It was, however, reserved for Parker to fill the more important *rôle* of lieutenant in the development of the Huxleian system and to assist in carrying it beyond the experimental stage. At the time of his appointment laboratory appliances were lacking, and a practical teaching museum based on the type-system was a desideratum. Under instructions to supply these needs, Parker in due course entered upon the task with a will, his only materials a free-hand and an early set of proofs of Huxley and Martin's "Elementary Biology" (with the final revision of which he was largely entrusted, since the junior author was leaving for Baltimore), and in carrying the task to a successful issue he founded the first practical biological museum or teaching-collection on the now generally adopted type-system, the prototype of all those subsequently established at home and abroad, in some cases even to the measurements of the furniture. The Huxleian method of laboratory instruction in the course of its development at headquarters has witnessed no change on the zoological side at all comparable to the inversion in the order of the work originally prescribed—*i.e.* the substitution of the anatomy of a vertebrate for the microscopic examination of a unicellular organism as the opening study, and this we owe entirely to Parker. As one privileged at the time to play a minor part, I well recall the determination in Parker's mind that the change was desirable, and in Huxley's that it was not. Again and again did Parker appeal in vain, until at last, on the morning of October 2, 1878, he triumphed. Dyer and Vines were Parker's more immediate associates in the early work of development of the Huxleian laboratory-system; and among the persons who studied under him as it progressed now occupying prominent positions in the biological world, may be named F. E. Beddard, A. G. Bourne, G. C. Crick, J. J. Fletcher, Patrick Geddes, Angelo Heilprin, C. H. Hurst, C. Lloyd-Morgan, Daniel Morris, R. D. Oldham, H. F. Osborn, W. B. Scott, T. W. Shore, Oldfield Thomas, and H. Marshall Ward. Parker's first paper ("On the Stomach of the Fresh-Water Crayfish") and his first book ("Zootomy") were alike a direct outcome of the undertaking, and the scheme for his "Lessons in Elementary Biology," formulated while still he was in London, was similarly begotten of his experience during its development, which oft formed the topic of conversation as he and I in the late '70's sat working side by side. Nor must it be forgotten that Parker rendered Huxley commendable aid in the production of his wonderful book on "The Crayfish." I venture to think that in recognition of all this Parker has established a claim to distinction in connection with the educational work of his great master second to that of none other; and when it is remembered that the unparalleled activity among botanists and zoologists during the last two decades has rendered it impossible for one man to efficiently teach the two subjects from a professorial chair, in the manner originally laid down under the Huxleian dispensation, Parker's name will occupy a unique position in the history of this, as that of the only man prominently associated with its inception who taught both subjects to the end of his career.

To the task of founding the Huxleian teaching-collection, moreover, is due Parker's interest in the work of the preparator, which led to his being the first person to successfully prepare and mount in a condition fit for prolonged display cartilaginous skeletons in a dry state. Under Parker's curatorship the Otago University Museum advanced by leaps and bounds, and while to his reputation as a teacher and investigator he thus added distinction as a conservator and administrator in zoology, he attained also a reputation in botany both as a manipulator and discoverer. He came upon the botanical platform at the time when Alfred Bennett and Dyer were at work upon the English translation of the third edition of Sachs's monumental "Lehrbuch der Botanik," and when the methods of that great man, already introduced into Britain by McNab, were by these botanists and their associates becoming established. For Parker, however, carrot-drill had little charm, while to his æsthetic nature glycerine and gold-size were messy and distasteful. He was at the time repeating the work of Nicholas Kleinenberg on *Hydra*, busy with osmic acid and cocoa-butter, and the well-known results of his labours led him to apply the method to the treatment of plant tissues, with the result that through a short paper communicated to the Royal Microscopical Society in March 1879, he ranks as one of the first to apply the modern dry methods of micro-chemical technique to vegetable histology. As a discoverer in botany he will remain memorable for having first directed attention to the existence of sieve-tubes in the marine algæ (*Macrocystis*) in a short communication to the *Transactions* of the New Zealand Institute for 1881.

Truly is his a great record, worthy his noble character and his association with a Huxley! but while the world will cherish his memory for that which he achieved, those who knew him feel that by his death something more than a link with the historic past has gone, and that they have lost a true friend, a noble man, an example. In the autumn of 1892 Parker came home on a visit. Soon after his return his wife died, and this event probably helped to bring on an illness which showed itself formidably about two years ago. Recurrent attacks of influenza, the last of which rendered him prostrate for three months, told severely upon his health and strength; but despite all, following the example of his beloved father, he worked on whenever he could, patient under suffering and affliction the like of which has killed many a man, beautiful in his unselfishness and lack of ostentation, loving, and sympathetic. On October 26 last, he had recovered sufficiently to start on a journey of some forty miles to visit a friend at Shag Valley, in company with his eldest sister, who for several years had lovingly shared his anxieties and administered to the needs of his three boys. While half-way onwards he became so prostrate that a halt was necessary, his friends deeming it advisable to take him towards home again. He reached only as far as Warrington, where he became weaker and comatose, and passed peaceable away on Sunday, November 7, at one a.m. He was buried there two days later, in the presence of sorrowing friends, a few among the many by whom he was universally beloved.

G. B. HOWES.

NOTES.

FEW men of science appear in the list of New Year honours. The honour of Knighthood has been conferred upon Prof. George Brown, C.B., Consulting Veterinary Surgeon to the Board of Agriculture; Mr. Ernest Clarke, Secretary to the Royal Agricultural Society; Dr. John Struthers, late President of the Royal College of Surgeons of Edinburgh; and Dr. John Hatty Tuke, President of the Royal College of Physicians of Edinburgh. Prof. Gardiner, Dean of the Faculty of Medicine, Glasgow University, has been promoted to be Knight Commander of the Order of the Bath (K.C.B.), and Prof. D'Arcy Thompson, British delegate at the recent Conference on the Bering Sea Fisheries, has been appointed a Companion of the same Order (C.B.). Mr. James Dredge, one of the editors of *Engineering*, has been made a Companion of the Order of St. Michael and St. George (C.M.G.), for services in connection with the Brussels Exhibition; and Major R. H. Brown, of the Egyptian Irrigation Department, has been given the same honour.

MR. ALEXANDER AGASSIZ, as we learn from his recently issued report on the Museum of Comparative Zoology at Harvard College, U.S.A., for the past year, has planned to pass the greater part of the present winter in studying the coral reefs of the Fiji Islands. He will be accompanied by Dr. Woodworth and Dr. Mayer as assistants. The steamer *Yaralla* has been chartered in Sydney for the expedition. In addition to the usual apparatus, for photographic purposes, for sounding and dredging, and for pelagic work, Prof. Agassiz takes with him a complete diamond-drill outfit, and hopes to find a suitable locality for boring on the rim of one of the atolls of the Fijis. The boring machinery will be in charge of an expert sent by the Sullivan Machine Company, from whom the machinery is obtained. The Directors of the Bache Fund have made a large grant towards the expenses of this boring experiment.

THE Sydney meeting of the Australasian Association for the Advancement of Science opens to day, under the presidency of Prof. A. Liversidge, F.R.S. A large number of papers are down for reading before the various sections, and we hope to give some account of them later. The evening lectures are by Prof. W. Baldwin Spencer, on "The Centre of Australia"; Sir James Hector, K.C.M.G., F.R.S., on "Antarctica and the Islands of the Far South"; and Prof. R. Threlfall and Mr. J. A. Pollock, on "Electric Signalling without Wires."

WE regret to announce the death of Major-General Edward Mounier Boxer, F.R.S., for many years Superintendent of the

Royal Laboratory at Woolwich. General Boxer was elected a Fellow of the Royal Society so long ago as 1858.

THE deaths are announced of Mr. Arthur Kammermann, astronomer at the Geneva Observatory; Dr. Eugen Zintgraff, African explorer; and Dr. Max Graf von Zeppelin, zoologist at Stuttgart.

A LIFE of Pasteur, written by Prof. and Mrs. Percy Frankland, will very shortly be published by Messrs. Cassell and Co. The volume will form the latest addition to the Century Science Series.

PRINCE ROLAND BONAPARTE has been elected a Correspondant of the Lisbon Academy of Sciences and of the Bologna Academy of Sciences.

THE new number of the invaluable *Minerva Jahrbuch der gelehrten Welt* has for the frontispiece a fine reproduction of a portrait of Dr. Nansen.

THE Paris correspondent of the *Times* states that the statue of Jules Simon, to be executed by M. Fremiet, will probably be erected in the Place de la Madeleine, near which he lived, and will supersede the fountain now standing there.

WE learn from *Science* that a resolution has been introduced in the House of Representatives appropriating 20,000 dollars for the representation of the United States at the International Fisheries Exposition to be held at Bergen, Norway, from May to September of next year.

THE British Institute of Public Health will be styled in future the Royal Institute of Public Health, and Her Majesty the Queen has accepted the office of patron. The Council of the Institute has conferred the Harben Gold Medal for 1898 upon Lord Playfair, and has appointed Prof. W. R. Smith the Harben Lecturer for the year 1899.

INVITATIONS are being sent out for the forthcoming International Congress of Zoology. A Committee of Reception has been formed in Cambridge, where the Congress will meet on August 23, 1898. An International Congress of Physiologists will be held at the same time in Cambridge. It is proposed at a later date to distribute further information on the more important subjects which will be brought forward for the consideration of the Congress.

THE personal estate of the late Mr. Alfred Nobel has been valued at 434,093*l.*, of which amount 216,901*l.* is in England. After a number of personal bequests have been made, Mr. Nobel's will stipulates that the capital of the whole of the remaining realisable property is to form a fund, the interest from which is to be annually divided in five prizes to those who during the preceding year have done most for the benefit of humanity. The interest is to be divided into five equal parts, which are to be awarded in prizes as follows: (1) To him who within the department of natural philosophy has made the most important discovery or invention; (2) to him who has made the most important discovery or improvement in chemistry; (3) to him who has made the most important discovery within the department of physiology or medicine; (4) to him who in literature has produced the most excellent work in an idealistic direction; and (5) to him who has worked most or best for the fraternisation of the nations and for the abolition or diminution of standing armies, as also for the promotion and propagation of peace. The prizes in physics and chemistry are to be awarded by the Swedish Academy of Sciences, for physiological or chemical work by the Carolinian Institution in Stockholm, for literature by the Academy in Stockholm, and for the propagation of peace by a committee of five persons to be elected by the Norwegian Parliament. The will continues:—"It is my express will that at the distribution of prizes no regard is to be paid to any kind of nationality, so that the most worthy competitor may receive the prize whether he is a Scandinavian or not."

THE Russian Institute of Experimental Medicine, at St. Petersburg, held its seventh annual meeting on December 20, 1897. The Institute consists of six scientific sections and one practical section, and during the past year no less than 120 persons took part in its regular work, which is carried on in the departments of biological chemistry, physiology, bacteriology, pathological anatomy, general pathology, and epizootic diseases. Sixty-five papers—some of them of high scientific value—were published by the scientific staff of the Institute. In addition to this, no less than 25,000 bottles of diphtheria serum, 800 bottles of anti-streptococcus serum, and 300 bottles of anti-staphylococcus serum were sent out from the Institute during 1897—making a total of 138,000 bottles of anti-diphtheria serum, and 15,000 bottles of malleine and tuberculine that were distributed within the last three years. Of persons bitten by rabid animals, 277 were under treatment, the percentage of deaths having been only 0·7. The serum treatment of the bubonic plague, the prophylactic measures against it, and the preparation of anti-plague serum were the subject of special work during the year, and its results were summed up in a paper which was read at the annual meeting by Prof. A. A. Vladimiroff.

THE following are the arrangements for lectures during January at the Imperial Institute. These lectures will be open free to the public, without tickets, seats being reserved for Fellows of the Imperial Institute and persons introduced by them. Monday, January 10, "Western Australia: its growth and possibilities," by Mr. H. C. Richards, M.P.; Monday, January 17, "South Africa, from the Cape to Ngamiland," by Mr. H. A. Bryden; Monday, January 24, "New Brunswick—Past and Present," by Mr. C. A. Duff-Miller; Monday, January 31, "Through the Gold Fields of Alaska to Bering Straits," by Mr. Harry de Windt.

AT the recent annual meeting of the Paris Academy of Medicine (says the *Lancet*) a report was presented upon the prizes awarded in 1897. The François Joseph Audiffred prize, which consists of 24,000 francs to be awarded to him who shall have, in the opinion of the Academy, discovered a really curative or preventive remedy against tuberculosis, has not been awarded. The offer holds good for twenty-five years, starting from April 2, 1896. Another prize not awarded was the Chevillon prize of 1500 francs offered to the writer of the best work upon cancerous affections—but a consolation prize of 500 francs was given to Dr. Livet for his work on the subject.

MR. JOHN W. BARBOUR, writing from Bangor, Co. Down, Ireland, informs us that an albino lark—believed to be a skylark—was shot in that district on December 27, 1897.

MR. B. WOODD-SMITH calls our attention to the following paragraph, which appeared in the *Whitby Gazette* of December 17:—"A splendid meteoric display was witnessed in the eastern heavens on Sunday night [December 12], shortly before eight o'clock. The meteors, which appeared of various colours, were of great brilliance, and illumined the sky with an effulgence greatly surpassing that of the clear and almost full moon shining at the time. About the time of the display, a sound like that of thunder was heard." Further information with reference to these observations would be of interest.

DR. R. F. SCHARFF records, in the *Irish Naturalist*, the discovery of some remains of the wild horse (*Equus caballus*) in Ireland. The remains consist of the occipital part of a skull and the posterior part of another. Both of these were forwarded to Dr. Scharff, who decided that they evidently belonged to horses, but to specimens of very small dimensions—certainly not larger than an ass. The skulls were discovered, when making a drain in Major Moore's property near Naas (Co. Kildare), resting on the gravel beneath the bog. The remains therefore probably belong to wild horses, which are known to have inhabited Ireland as contemporaries of the Irish Elk. Dr. Scharff points out that all the remains of the wild horse hitherto discovered in Ireland, viz. in Shandon Cave and many Pleistocene deposits, point to the fact that it was of small stature.

An interesting glimpse of Huxley's home-life is given in the *Century Magazine*, by his son Mr. Leonard Huxley, and it reveals another aspect of his gentle and loving character. After his retirement in 1885, the extra leisure permitted his affection for children to have full play. Of one of his grandsons, Julian, he was very fond, and the following incident shows how he would give rein to his humour and wisdom to please a child. Julian had been reading the "Water Babies," wherein fun is poked at his grandfather's name among the authorities upon water babies and water beasts of every description. The book is illustrated by a picture showing Huxley and Owen examining a bottled water baby under big magnifying glasses, so Julian thought he would consult his grandfather upon the matter. He therefore wrote: "Dear Grandpater—Have you seen a water baby? Did you put it in a bottle? Did it wonder if it could get out? Can I see it some day?" Julian's interrogations are worthy of a Huxley, and this is the reply they received: "My dear Julian, I never could make sure about that water baby. I have seen babies in water and babies in bottles; but the baby in the water was not in a bottle, and the baby in the bottle was not in water." Other stories are told to illustrate Huxley's sympathies with, and tenderness to, the little ones. As is well known, cats were great favourites with him. Like Mahommed who, rather than disturb his cat, cut off the sleeve of his robe on which it had gone to sleep, Huxley would not turn a cat out of his study chair, but would himself sit in a less comfortable seat and leave the cat in peace. At Eastbourne he gave most of his time to gardening, and all through the last years of his life the garden and the flowers were his greatest source of pleasure.

We learn from the Annual Report of the Director of the Royal Alfred Observatory at Mauritius, for the year 1896, that a new series of publications has been commenced; a separate volume, entitled "Mauritius Magnetical and Meteorological Observations," will contain the daily, monthly and annual values of the principal elements, and will be substituted for the various tables which have hitherto appeared in the Mauritius Blue Book. The rainfall was 18·58 inches above the average for the last twenty-two years. After heavy floods in February (25·94 inches in four days), followed by excessive rain during a severe thunderstorm on May 7, severe droughts were experienced between September and December. An examination of the diurnal variation of rainfall for 1888–96 shows a double oscillation, the maxima occurring at 4h. a.m. and 3h. p.m., and the minima at 10h. a.m. and 8h. p.m., these hours corresponding nearly to the epochs of minimum and maximum barometric pressure. The mean temperature was nearly normal, being only 0°·3 below the average. As usual the logs of ships arriving at the island were copied, so far as the observations related to the Indian Ocean. Photographs of the sun were also taken daily, when the weather permitted, and these have been forwarded to the Solar Physics Committee.

A useful series of records of the Hereford earthquake of December 17, 1896, as it affected the county of Hertford, is contained in a paper by Mr. H. G. Fordham (*Hertfordshire Nat. Hist. Soc. Trans.*, vol. ix., 1897, pp. 183–208). In his summary of the observations, Mr. Fordham notes that the earthquake was felt more or less distinctly over the whole county, though it was naturally more marked on the west side than on the east. There is no clear difference in its recorded effects at places situated at different altitudes and on different rock-formations. While there is a general agreement as to the swaying or rolling character of the movement, there is a conflict of evidence as to accompanying sound. In a large number of cases, a rumbling sound is recorded; but, on the other hand, some very competent observers speak positively as to the absence of noise. There is the usual diversity in the personal impressions with regard to the direction of the movement, with a balance of numbers, however, in favour of a movement along a west and east line.

The lately issued sixteenth volume of the *Bulletin* of the United States Fish Commission contains an excellent report on the Russian Fur Seal Islands, prepared by Mr. Leonhard Stejneger, of the U.S. National Museum, which should be studied by every one interested in the question. Mr. Stejneger, who has visited the Commander Islands twice—first in 1882–83 in the palmy days of the fur seal industry, and again in 1895 during its decline and fall, and who is a well-known expert on the subject, comes to the conclusion that the only measures likely to stop the ultimate destruction of the fur seals of these islands is the "total and absolute prohibition" of pelagic sealing in the North Pacific for at least six years, and, after that period, the total prohibition of pelagic sealing within a zone of 150 miles from the islands. These measures would, no doubt, be effectual if they could be carried out, and would be much for the benefit of the Russian Seal-skin Company, which holds the lease of the islands; but Mr. Stejneger does not explain how it is proposed to stop seal-catching in the free and open ocean, nor whether the Russian Company, to which the benefit would accrue, is prepared to pay for it.

Mr. J. Cosmo Melvill has reprinted from the *Journal of Conchology* his presidential address upon the principles of nomenclature and their application to the genera of recent Mollusca. It contains an historical sketch of the subject as regards pre-Linnæan authors which will be useful, if, as we understand, nomenclature is to be one of the subjects for discussion at the meeting of the International Zoological Congress at Cambridge in August next. Mr. Melvill gives also a useful list of genera of marine Gastropods about the names of which some differences of opinion have existed, and indicates those which he thinks ought to be adopted.

It is well known to psychologists that some persons experience a sensation of colour in association with certain sounds, the colour seen being definite and invariable for the same sound. Dr. W. S. Colman describes a number of these cases of colour-hearing in the *Lancet* (January 1). Cases of this kind usually fall into two groups. In the first there is a crude colour sensation, often very beautiful, associated with certain sounds such as each of the vowel sounds, musical notes, or particular musical instruments. The appearance is usually that of a transparent coloured film similar to a rainbow in front of the observer, but not obscuring objects. In the second group there are colour sensations whenever letters or written words (symbols of sound) were spoken or thought of, so that when a word is uttered the subject visualises the letters, each having a distinctive tint. A study of the subject leads Dr. Colman to regard the phenomena as "associated sensations" analogous to the cutaneous sensation of shivering in certain parts of the body, varying in different individuals, which is experienced at the sight or thought of an accident, or at the sound of the squeak of a slate-pencil. The tints excited are very definite and characteristic, each for its own sound. They do not vary as time goes on. The colours are scarcely ever the same in two individuals. This is very clearly shown in two coloured diagrams which accompany Dr. Colman's paper. The first diagram shows the tint excited by the spoken vowel sounds in twenty-one individuals, while the second shows the tints of the colour sensations excited by the letters of the alphabet in seven individuals. Dr. Colman does not, however, give the colour sensations excited by numbers. The writer has tested a boy at intervals within the past four years, and has found that each numeral is associated with a colour as follows:—1, black; 2, white; 3, yellow; 4, red; 5, green; 6, grey; 7, mauve; 8, light grey; 9, brown; 0, black. These associated colours have remained the same throughout the period.

A new monthly journal of mechanics and electricity for amateurs and students has just made its appearance under the title of *The Model Engineer*. The periodical is intended particularly for amateurs who take up mechanical or electrical work as a hobby.

The additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, presented by Mrs. R. H. Padbury; a Suricate (*Suricata tetradactyla*) from South Africa, presented by Mrs. Soames; a Spectacled Bear (*Ursus ornatus*, ♂) from Colombia, a Spotted Cavy (*Cœlogenys paca*) from South America, presented by Mr. William Crosley; three Brown Capuchins (*Cebus fatuellus*), a Blue and Yellow Macaw (*Ara ararauna*), a Red and Yellow Macaw (*Ara chloroptera*) from South America, deposited; a Naked-throated Bell-Bird (*Chasmorhynchus nudicollis*) from Brazil, two Noisy Pittas (*Pitta strepitans*) from Australia, purchased.

OUR ASTRONOMICAL COLUMN.

Winnecke's Comet.—As announced in this column a fortnight ago, Winnecke's periodic comet is shortly due at perihelion, and therefore might be expected to be picked up at any time. Such has been the case, for Prof. Perrine telegraphs from the Lick Observatory that it was found on January 1, being only feebly visible. Its position then was R.A. 15h. 19m. 42·5s., Decl. −3° 58′ 34″ S.

Arrival of Eclipse Parties at Bombay.—Reuter's correspondent at Bombay states that Mr. E. W. Maunder, Mr. C. Thwaites, and the Rev. J. M. Bacon, with the parties under their direction sent by the British Astronomical Association for the observation of the total solar eclipse on the 22nd inst., have arrived there. The different observing stations will be as follows:—Mr. Maunder and Mr. Thwaites will be stationed at Talni, on the Great Indian Peninsula Railway, between Amraoti and Nagpur; the Rev. J. M. Bacon at Baxar. The Astronomer Royal and Prof. H. H. Turner, forming one of the official parties sent out by the joint committee of the Royal Society and the Royal Astronomical Society, will be stationed at Sahdol, between Katni and Bilaspur. The observing party from the Government Observatory at Madras, under the direction of Prof. Michie Smith, will be at Indapur.

Mont Blanc Observatory.—The closing of the year brings to hand the reports from many observatories, and not the least interesting is that by M. J. Janssen, in *Comptes rendus* No. 24, "On the work done in 1897 at the Mont Blanc Observatory."

During 1897 the principal work has been the determination of the quantity of heat received by the earth from the sun, or the *solar-constant*, as it is called.

The meteorological conditions have not been very favourable, and M. Janssen was compelled to direct observations and expeditions from Chamonix, only reaching there with difficulty, having seriously injured his left leg, which made an ascent of Mont Blanc quite impossible for him. The observations were, therefore, made by M. Hansky—first at Brévent, again at the Grands Mulets, and finally at the summit of Mont Blanc, at the observatory.

From these observations a *solar-constant* of nearly 3·4 calories has been deduced; that is to say, a value notably higher than that obtained before. This, M. Janssen thinks, will be still further increased, for the more deeply the question is studied the more one ascertains the complexity of the elements which enter into it. For instance, of the radiations which strike the earth, it is those having wave-lengths of large and small periods that undergo the greatest absorption in the atmosphere; those with a mean wave-length corresponding to the most luminous part of the spectrum are propagated with the least relative loss. As a result of this, if the transmission of heat in a zenithal direction be deduced from observations made through a great thickness of the atmosphere, it will give a value much too high, and hence one much too small for the solar radiations outside the limits of our atmosphere, which value is the solar-constant. Again, the presence of water vapour and dust particles, whether of snow or other matter, all give rise to disturbing effects which influence the results. To obtain precise indications of water vapour the spectroscope has been used, and for the dust particles and snow clouds M. Cornu's form of polariscope has been employed with success.

From these results it can be seen that it is desirable the observations should be made with as little atmosphere intervening as possible; that is, at high altitudes—in balloons even, if sufficiently precise instruments could be used in these regions of the atmosphere. Nevertheless, if stations such as that of Mont Blanc do not offer comparable altitudes with those which balloons can reach, in return they permit the use of instruments more delicate and precise, giving trustworthy results.

Photography of Unseen Moving Celestial Bodies.—Quite recently Prof. Barnard showed in *Astr. Nach.*, 3453, how it might be possible to photograph an "unseen moving but known celestial body," as, for example, unseen comets, or the swarm of meteorites giving rise to the November shower. The method, it may be remembered, was to watch with a guiding telescope and keep an adjacent star on cross wires moving in the correct position angle at the proper rate, the movement to be produced by an arrangement of watch-work. In *Astr. Nach.*, 3467, Herr Josef Jan Fric, of Prague, gives an account of a somewhat similar method in which the photographic plate or object glass is moved in the requisite direction. The holder is driven by a fine screw, which derives its motion from the intermittent action of a ratchet wheel moved by a "powel," which in turn is actuated at will by an electro-magnet. The length of stroke can easily be altered so as to give any varying motion which may be necessary, but of course, in consequence of the discontinuity of the movement produced in this way, the change in the position of the plate must be so small as not to interfere with the perfectness of the image photographed.

Astronomical Annuals.—Perhaps the most useful annuals for use, either in a well-established observatory or by amateurs, are: the *Companion to the Observatory* and the *Annuaire Astronomique et Météorologique;* and if these two could be compounded together, they would form a most desirable and complete compendium of astronomical data. The former confines itself chiefly to tabular matter giving data for finding the planets and their satellites with their respective phenomena, occultations, and eclipses. In addition to these, and perhaps the most important section, as it is not readily found elsewhere, is the ephemeris for physical observations of the sun, mean places, and maxima and minima of variable stars of all periods, and also the radiant points of the principal meteor showers of the year.

The latter publication, by M. Camille Flammarion, is in its thirty-fourth year, and while treating of astronomical events in a popular way, it gives numerous diagrams, and has many interesting features. The calendar, detailing observations to be made for each day, has proved itself most useful, as also have the charts of the positions of the planets.

PHOTOGRAPHIC MEASUREMENT OF HORSES AND OTHER ANIMALS.

VALUABLE horses are habitually photographed by professionals and amateurs, and beautiful portraits of them appear in newspapers; notably in *Racing*, in the *Horseman* of the U.S.A., in *Le Sport Illustré*, and in other similar periodicals. I am informed that in shows of pedigree stock it is frequently required that the prize-winners should be photographed, it being of obvious importance that the appearance of the progenitors of animals should be known before selections are made for pairing. It seems, then, that if photographs of horses and other pedigree stock could be rendered available for strict scientific studies in heredity, the material is copious, and as it would in time extend through many generations, should far exceed in value anything that is now procurable for those purposes. But all depends on that "if." The basis of science is exact measurement, for which the existing photographs are unsuitable. My present object is to show that by paying strict regard to conditions of a simple kind, an ordinary photograph will be transformed from a mere picture into a record of real scientific value; so that if photographs should hereafter be habitually made of pedigree stock (not only of horses) under those conditions, and be afterwards published, a mass of material would quickly accumulate, sufficient to advance the science of breeding far beyond the point at which it now stands. Artistic photographs are not to be discouraged. Their object is to exhibit animals in their more attractive positions, as by inclining the fore part of their bodies to the camera when it is desired to make the shoulders look larger than they are. What I desire is that other and inexpensive photographs should be procurable, which shall be suitable for exact measurement.

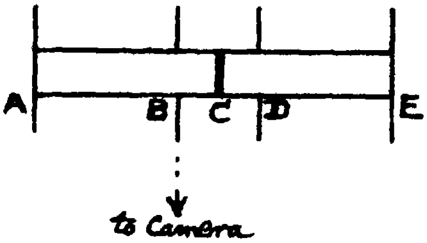

FIG. 1.

All that is asked for is a strip of hard level ground, on which a rectangle is laid out of some 8 or 9 feet (say 100 inches) long and 20 inches wide, and otherwise marked, and that the camera shall be directed squarely towards a certain point in it, as shown by the diagram (Fig. 1). The horse is to be led to the rectangle, and kept in it, taking care that all his feet stand within its margins, that the cross-line at C lies clear of his front and hind legs, and that the tip of every hoof and each corner of the rectangle is visible from the camera. The appearance of the horse standing upon the rectangle, as seen in the photograph, would be this (Fig. 2), but the lines should be much more delicate. The camera should be placed on a line strictly at right angles to the side A E of the rectangle. When the horse's head, as in Fig. 2, is on the side of A, the perpendicular in question should be drawn from B, a point about a foot distant from C, and on the same side as A. Then the image of the horse fits, laterally, well into the field of the camera. When the horse's head is intended to be on the side of E, a symmetrically situated point D must be selected for the foot of the perpendicular on which the camera is to stand. The distance of the latter from the rectangle should be fully 20 feet.

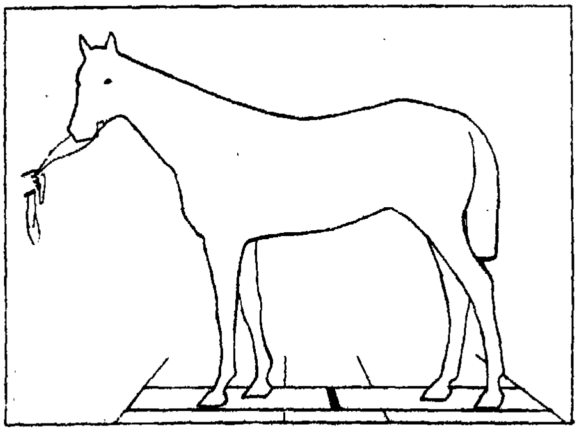

FIG. 2.

The camera having an adjustable back, must be slightly tilted downwards in order to get a good view of the feet, but its back must be kept *strictly vertical*. It would be a decided gain if the installation were so arranged, that the photograph should contain means of judging whether the plate in the camera had really been adjusted aright—that is, parallel to the vertical planes passing through the long sides of the rectangle. This can be accomplished by laying out the rectangle near the base of a wall, with its long sides parallel to it; then, driving two nails into the wall in the same horizontal line, hang a long string with weighted ends over them, the ends nearly touching the ground. If the two nails are well placed, the line will appear in the photograph, as running along the top and down the two sides of it, close to the margin. Then, if the plate has been rightly adjusted, the upper line in the picture will remain parallel to the long sides of the rectangle, and the two weighted ends will remain parallel to one another. Otherwise there will be convergence in one or both respects. The camera must be high, in order to show well the position of the horse's feet; 5 feet is perhaps the best height for it at a distance of 20 feet, then the perspective foreshortening of the width of the rectangle is such that its scale is one-quarter of that of its length.

Relative measurements can be made with accuracy on photographs taken under these conditions, between any visible points that are situated on the median plane, such as between the withers and the lower part of the chest below them, between the front and the back of the profile, and so on, but absolute measurements cannot be made because the distance between the camera and the median plane is not yet accurately determined. Much less can heights above the ground be measured, for in order to do so it is necessary first to determine the line at which the median plane of the horse intersects the ground, because it is to this line that the vertical measurements must be made. What is meant by "median plane," is the imaginary plane which passes lengthways and vertically through the spine of the animal, and which serves generally as a plane of reference. It cuts the ground half-way between the two pairs of hoofs, so that if the half-way position between the tips of the fore hoofs be called S, and that between those of the hind hoofs be T, then the intersection of the median plane with the ground lies along the line S T. For its accurate determination the animal should stand on hard ground, and the hoofs be so disposed that at least the tips of all four shall be visible from the camera, which must be well elevated so as to look down on them, as already described.

Beginning with the simplest case, namely that in which the median plane of the horse is parallel to the long sides of the rectangle, and also parallel to the plate in the camera, we are at once in a position to measure the height of the horse, its depth of body wherever desired, and its length. For by prolonging S T in the photograph until it cuts the ends of the rectangle in S′ and T′, a length equal to that of the line S′ T′ drawn on the median plane in any direction will correspond to the length of 100 inches objectively. We begin by measuring the lengths of S′ T′, and those of any other, say two, dimensions on the photograph. Call their several measurements s', a, and b, reckoning them according to the scale used throughout for that purpose, whatever the value of the units of that scale may be. Let x and y be the objective values of a and b, which have to be found;

$$\text{then } s' : 100 :: a : x \text{ and } :: b : y$$

$$x = \frac{100}{s'}a \qquad y = \frac{100}{s'}b,$$

so the coefficient $\frac{100}{s'}$ being determined, serves to convert these and all other measurements in this same median plane into their objective values. Those persons who possess Crelle's Multiplication Tables, can perform these little sums without effort and with great rapidity. In Fig. 2 the real length of the rectangle there represented happens to be only 80 inches. The measurements on the diagram are as follow:—(1) $s' = 21{\cdot}6$ mm.; (2) height of withers, 15·7; (3) height of lower side of chest, vertically below, 8·9; (4) height of rump, 16·2; (5) extreme length of body, 15·5. Whence the coefficient $= \frac{80}{21{\cdot}6} = 3{\cdot}7$, and the objective values are (2), 58·1 inch, (2-3) 25·1; (4), 59·9.

Before considering the effect of obliquity the following objection must be disposed of. It may be said that the protuberant sides of the animal will prevent its true outline being visible from the camera, for the reasons indicated by Fig. 3, which is an extreme case in which the camera, or eye, R is supposed to be very near to the side of an animal, so fat that his cross section has to be represented by a circle.

The summit of the outline as seen from R is H, giving the idea that the spine of the animal is as high as L, whereas it is really at K. The ratio of LO to KO is of course the same as that of LO/OR to KO/OR, that is to HO/OR; in other words as the tangent of L R O to the sine of the same angle. The values to be dealt with in reality, are very different from those in the diagram. OR is 240 inches and KO may be taken as 15 inches. It results that L R O is only 3° 35′. Now the tangent and sine of such a small angle are so nearly alike that LO : KO :: 100·00 : 99·85, which corresponds to a difference of less than 1/8th inch in a horse of 15 hands high, and is quite negligeable.

In some fat stock, however, the backs are flat like tables. Here some artifice would be necessary to obtain the true height, such as by fixing a stud of say 2 inches in height to a surcingle. The top of the stud would then be the point of measurement, and 2 inches would be subtracted from the result.

We now come to the effect of obliquity of the median plane of the horse to the long sides of the rectangle. The hoofs of a thoroughbred horse are some 4 inches wide, and 4 inches apart, so that the closest distance between either S or T, and the nearest side of the rectangle, is 6 inches; therefore the utmost cross distance between S and T is (20 – 12) or 8 inches, and the length of ST in a horse of 15 hands in height may be taken as 60 inches. Therefore the maximum obliquity within the strip is as 8 to 60, or 0·1333, which corresponds to an angle of 7° 39′.

The foreshortening of the length ST (= 60 inches) is such that its foreshortened value must be multiplied by the secant of 7° 39′ to obtain the unforeshortened value, that is by 1·009, which makes it nearly 1 per cent. longer. This is the greatest error to be feared under the conditions, and it is further much diminished by determining the actual obliquity. We can do this easily by measuring the distance lengthways between the points where ST produced cuts the opposite sides (not ends) of the rectangle. The further side of the rectangle affords the scale for reckoning distances from C along that line when produced; similarly the nearer side affords the scale for distances from C measured along and beyond itself. The cross distance between those points is known to be 20 inches, so the obliquity is easily found. The accompanying table may be found convenient. It applies with strictness only to objects viewed from a great distance, but is practically correct for much smaller ones.

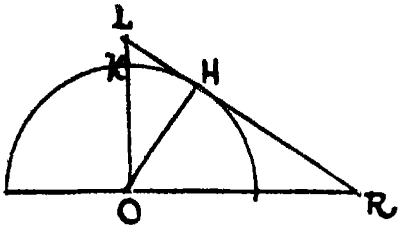

FIG. 3.

Obliquity.		Multiplier to convert fore-shortened values.	Corrections to be added to foreshortened measurements of			
			10 ins.	30 ins.	50 ins	70 ins.
	° ′		in.	in.	in.	in.
1 in 7	8 12	1·0103	0·100	0·20	0·50	0·70
,, 10	5 43	1·0050	·050	·15	·25	·35
,, 15	3 49	1·0022	·022	·07	·11	·15
,, 20	2 52	1·0012	·012	·04	·06	·09
,, 25	2 18	1·0008	·008	·02	·04	·06
,, 30	1 55	1·0006	·006	·02	·03	·04

The mean scale for the slightly oblique median plane is the perspective length of the rectangle at the point where a line drawn through the middle of ST cuts the perspectively viewed ends of the strip. It is unnecessary to attempt greater minuteness, as by determining the vanishing point (the position of which is given by prolonging two or more of the cross-lines upon the ground to their points of common intersection in the photograph), and then employing the further methods known to draughtsmen in perspective. Much could be written of which it is unnecessary to speak here, because it is a condition that the obliquity shall never be great. A strict attention to the elementary requirements laid down above, makes the problem of measurement extremely simple; otherwise it becomes complex and troublesome.

The next point to be considered is the method of measuring between points situated on the side of the horse, such as from the haunch bone to the shoulder. I shall speak of these in general terms only, because the most suitable points for measurement have yet to be determined. Whatever they be, it is a great assistance, before photographing the horse, to mark the points to be measured either by chalk, or more neatly by a disc of gummed paper, the size of a shilling, wetted and stuck on. Veterinary-Captain F. Smith has used both these plans. It is also an excellent plan to prick through these points in the photograph, and through a piece of paper laid below, and to measure between the prick holes. The general principle of dealing with these measurements is to find a *mean* correction suitable to each distance, when those distances have been calculated as if they were situated on the median plane. The lateral deviation from that plane of each one of these points, ranges within narrow limits, when the height of the horse is taken as unity. The mean deviation even of either protuberant haunch bone from the median plane between them, is much under 20 inches in a horse of 60 inches (15 hands in height). The mean range of this deviation in different horses of that height, judging from what occurs in anthropometric measurements, is probably very much under an inch, and its extreme range in ordinary cases would be under 2 inches. Extraordinary cases of massive or slender build would be betrayed by the photograph itself, and could be allowed for. It seems, then, that after the desirable points had been determined, between which measurements might be wanted, it would be a straightforward piece of work to make numerous measurements between them in different horses, and to draw up the suggested table of corrections for 2 or 3 different positions in the rectangle.

The head and neck can hardly be measured on the above principles, as it is very difficult to ensure that their median plane should be the same as that of the body. A strip of card chequered with inches, alternately white and black, and fastened to the head stall, affords a serviceable scale, and is by no means unsightly.

From measurements obligingly procured for me by Dr. MacFadyean, the Principal of the Royal Veterinary College at Holloway, the measurements being repeatedly made of the same horses by different pupils, I learnt two things. One was that horses of the same class vary among themselves as much as men. In short, they could be identified by a Bertillon method. The other was that the fallibility of a measurer was considerable. I think that measurements made on a half-plate photograph, under the conditions I have described, would on the whole be more trustworthy than direct measurements made with a tape or callipers, especially on fidgety horses.

FRANCIS GALTON.

THE MAGNETIC PROPERTIES AND ELECTRICAL RESISTANCE OF IRON AT HIGH TEMPERATURES.

THE magnetic properties of iron and, to a lesser extent, of the associated metals, nickel and cobalt, have always been a fascinating subject of study. Possessed by these three metals alone, these properties, so peculiar and so different from any of the other known properties of matter, have imparted to the study of these so-called magnetic metals a special charm and interest, apart from that excited by the vast industrial importance of at least one of them.

Among the very early inquiries into the nature of magnetism there were not neglected experiments on the effect produced by change of temperature. Three centuries ago, Gilbert recorded the observation that a piece of iron or steel, if heated more strongly than up to a full red heat, ceased to be attracted by a magnet, though it regained its previous magnetic qualities on cooling below that temperature.

Until comparatively recently, however, accurate magnetic measurements, even at ordinary temperatures, could alone be made on *permanent* magnets and the forces acting on their poles. The capability of acquiring *temporary* or induced magnetism when near a magnet, which is the characteristic property of soft iron, could not be subject to strict measurement until it was shown, firstly, how a given specimen of iron could be uniformly magnetised in a uniform magnetic field; and secondly, how both the magnetising force of that field, and the consequent magnetisation of the iron could be measured. We know of only one way of completely satisfying the first condition: namely, by covering a ring-formed specimen (whose outer diameter but slightly exceeds the inner) with a uniform layer of insulated wire carrying an electric current, thus forming a ring-magnet with no disturbing poles. And Faraday's researches on electro-magnetic induction have furnished us with a method, at once accurate and convenient, of determining the magnetisation of the apparently unmagnetised ring-magnet, *i.e.* by the use of a "secondary winding" or outer layer of insulated wire, connected with a "ballistic" galvanometer. Knowing then the intensity of magnetisation called up by a given magnetising force, we can, from their ratio, express the facility with which the iron takes up magnetic induction, or, in other words, its magnetic *permeability*.

To apply this method to the measurement of permeability at high temperatures, both the magnetising and the secondary winding must be so insulated as to be uninjured by the heating; and further, the thermometer or pyrometer, which measures the temperature, must be placed inside the ring, so as to measure the actual temperature of the iron.

Among the earlier important researches on magnetic properties at high temperatures, that of Baur of Zürich, in 1879, should be mentioned. He experimented simply on an iron bar heated in a furnace, and thence rapidly transferred to the interior of a straight magnetising coil. Not, however, till 1889 was it shown by Dr. Hopkinson, in his classical researches, that the ring-magnet method could be successfully applied to the measurement of permeability at high temperatures. The windings of the ring-magnets were in this case of copper wire insulated with asbestos; the heating was carried out in a gas furnace; and the rise of temperature of the iron core was deduced from the increase of the electrical resistance of the secondary winding.

Of the more recent researches, the most remarkable is that of M. Curie, published in 1895, describing experiments on the magnetic behaviour of a great variety of substances, at temperatures ranging up to a white heat. The method he adopted—that of finding how strongly the specimens were attracted, when placed near a powerful magnet, was well adapted to determine permeability in intense magnetic fields, but it is much inferior to the ring-magnet method, where the permeability varies much with the magnetising force, as is the case whenever the magnetic field is not intense.

In the course of some experiments on the subject of this article, the results of which have been recently published, I have endeavoured to approximate, where possible, more closely than previous experimenters to the ideal method which would be the outcome of the principles laid down above. The ring-magnet, whose core was the iron specimen to be tested at high temperatures, was made very small, measuring about one inch across. The temperature of this core was determined by means of an electrical thermometer *embedded in it*, consisting of a wire of pure platinum whose electrical resistance at any temperature had been previously determined, and whose resistance, therefore, if subsequently measured, gave its temperature, and hence also that of the iron core in which it was laid. Asbestos paper insulation, as had been used by former experimenters, was found to be very imperfect at high temperatures, owing largely to carbon deposited from the materials used in its manufacture. This difficulty was, after some trouble, overcome; but wherever a high degree of insulation was wanted, as in the case of the thermometer wire and secondary winding, it was found necessary to employ *mica*, though, as may well be imagined, the use of such an untractable material for such a purpose is beset with considerable mechanical difficulties.

Now, to find the magnetic condition of a sample of iron at a given temperature with any completeness, it is not sufficient merely to measure its permeability in various magnetic fields; the behaviour of the iron when subjected to what is called a "cyclic" process of magnetisation must be studied—the "hysteresis," or energy, absorbed in one double reversal of the magnetisation of each cubic centimetre of the iron, must be measured.

But the taking of so many observations requires time; and if, during this time, the temperature of the iron be not perfectly constant, all efforts at refinement in the magnetic measurements are thrown away. The heating of the ring must, then, be thoroughly under control. The method I adopted was an electrical one. The ring-magnet was furnished with an extra winding of asbestos-insulated platinum wire, so wound as to have no magnetising influence; and by passing through this wire a suitable electric current, heat could be generated in the ring at any desired rate. This method, however (the principle of which was adopted as long ago as 1888 by M. Ledeboer) is not used to full advantage unless combined with an effort to thermally isolate the body to be heated. Each ring-magnet was therefore thickly wrapped with asbestos, and supported in the centre of a closed and partially exhausted glass vessel (oxidation of the iron core was also in this way avoided).

This method of heating proved most satisfactory. The loss of heat by radiation and conduction being slight, the ring-magnet could not rapidly alter its temperature; and there is probably no way in which we can supply heat-energy to a body, which can compete with the electrical resistance method, either as regards constancy or control. For obtaining temperatures up to 1300° or 1400° C.—a white heat—this method, combined as far as possible with "thermal isolation," and an electrical method of measuring the temperature, should in the future prove of the greatest value in all cases where the physical properties of bodies at high temperatures require careful investigation.

The original intention of my experiments was to ascertain exactly in what way the specific electrical resistance of iron changes at and about the "critical temperature" at which the magnetic properties of iron so nearly disappear, so as to throw light if possible on the molecular state which we characterise by the term "magnetic." With this object the iron core of the ring-magnet was formed of a long insulated iron strip, among the turns of which the platinum thermometer wire was buried; and with this piece of apparatus simultaneous measurements of the magnetic qualities and electrical resistance of a sample of iron could be made with accuracy alike at low and high temperatures.

Let us now consider the magnetic changes which occur in soft iron when heated. At ordinary temperatures iron shows a kind of unwillingness, so to speak, to become *slightly* magnetised—its permeability under small forces is not great. Beyond a certain limit, however, it exhibits the greatest readiness to become further magnetised, and continues to have a high permeability until magnetised very strongly. But from this point it begins to show signs of magnetic *saturation*, and ultimately refuses to be further magnetised without the application of very great force.

Now, as the temperature of the iron is gradually raised, it is found that practical magnetic saturation takes place sooner and sooner. Iron refuses to become so strongly magnetised at higher temperatures. Thus the permeability in strong magnetic fields falls off as the temperature rises—very slowly at first, then more rapidly, till, near the "critical temperature," the permeability rapidly drops to quite a low value.

On the other hand, in weak magnetic fields, the behaviour of iron up to within a few degrees of the "critical temperature" is precisely opposite. The permeability *rises* with the temperature—at first slowly, then above 500° C. with ever increasing rapidity, until at last that lack of susceptibility to small forces disappears, and iron shows itself just as amenable to magnetic influence in small magnetic fields, as in the larger ones, where the maximum permeability occurs.

At this temperature—say 15° below the critical temperature (about 750° C.—a red heat), iron possesses all those qualities at once which are sought after by the transformer maker:—Practical absence both of hysteresis and of eddy currents (the latter owing to the greatly increased electrical resistance), and a permeability nearly four times as great as that attainable in commercial transformer iron. So magnetic, indeed, is the iron, that even the earth's magnetic field, in the direction of its greatest intensity, is enough to induce strong magnetisation ($B = 5000$), in fact almost saturate the iron (for which at this temperature a relatively low induction suffices). The behaviour of a compass needle near a slowly cooling ingot of cast steel, should be rather interesting, for just below the critical temperature the vertical ingot must behave as a very powerful magnet indeed.

For all the lesser magnetic fields, there is a temperature of maximum permeability which is nearer to the critical temperature the smaller the magnetic field. But *at* that temperature the magnetic qualities in almost all fields practically vanish. Hence, when the magnetising force is very small, the change from enormously magnetic to almost non-magnetic takes place with extreme suddenness.

Above the critical temperature, iron is but feebly magnetic; yet it is still much more readily affected by a magnet than most other feebly magnetic bodies. Not till a white heat is reached, do the magnetic qualities of iron become imperceptible.

It is not easy in an article like the present to deal with the changes which occur in the electrical resistance of iron, but the following remarks may be of interest:—

The experiments of Dewar and Fleming have shown that at a temperature of - 200° C. the specific electrical resistance of iron is extremely low. Throughout the range of temperature included between that extreme of cold and the critical temperature, about + 780° C., the resistance rises at a steadily increasing *rate*, so that at the latter temperature it is over 150 *times* as great as at the former: far in excess of that of any known alloy at ordinary temperatures (crystalline metals and their alloys excepted), and about equalling liquid mercury for high specific resistance. On still further raising the temperature of the iron, it is found that the *rate* of rise of resistance, instead of further increasing, very rapidly falls off till, at a white heat, the resistance of iron increases only slowly with the temperature.

It has long been known that this *increasing rate of rise* of resistance with temperature is a characteristic possessed by the magnetic metals alone. Here now we see that no sooner does the iron cease to be strongly magnetic than this quality disappears, and becomes exchanged for an opposite one, namely, a *decreasing* rate of rise of resistance with temperature. In some hitherto unpublished experiments on Hadfield's manganese steel (a non-magnetic steel which can be rendered magnetic by annealing), I have observed a precisely similar change of the resistance-temperature function to take place during the annealing of this steel, thus furnishing a second case of this obscure resistance-change accompanying the change from magnetic to non-magnetic, in one and the same sample.

The connection between magnetic and electrical properties is evidently not a very simple one, but in the face of these facts it is hard to deny that there is one; and it is only by trying to find out how the various physical properties depend upon magnetism that we may hope to arrive at a comprehensive explanation of that obscure but most interesting condition of matter.

DAVID K. MORRIS.

◆

EARLY MAN IN SCOTLAND.[1]

IN Scotland, as in other countries, man existed before the time of written history. The conditions under which his remains are found, and the works which he has left behind him, provide the data for determining their age, not absolutely or capable of being expressed in numbers of years, but relatively to each other.

Marked differences existed in the physical conditions of Scotland, and indeed in the northern parts of England also, as compared with the southern districts of England and the adjoining parts of France and Belgium at the first appearance of primeval man in those countries. It is the more necessary, therefore, that the conditions then prevailing in Scotland should not be overlooked.

No evidence sufficient to satisfy geologists has been advanced to prove that man existed in Britain during the period called Tertiary. So far, indeed, as Scotland is concerned, even if it were admitted that in other parts of the globe man had been on the earth during Tertiary times, there is little likelihood that his remains could have been preserved; for in that country the Tertiary is represented chiefly by volcanic rocks, and a few patches of sand and gravel with rolled sea shells belonging to the closing stages of that period.

From the careful study which geologists have given to the surface of Scotland, it is evident that at the commencement of the period termed Quaternary or Pleistocene, immediately succeeding the Tertiary, the whole of the country was covered with ice which formed a great sheet 3000 or 4000 feet thick in the low grounds, of which the lower boulder clay, or Till, as it is termed, was the ground-moraine.

As an upper boulder clay also occurs, which is often separated from the lower boulder clay by stratified deposits, some of which contained marine, and others fresh water and terrestrial organic remains, it is obvious that the Ice Age was not one uninterrupted period of continuous cold.[1] The lower and upper tills are the ground-moraines of independent ice sheets, each indicating a distinct epoch, separated by an interglacial period. The earlier epoch was that of maximum glaciation, and the ice sheet extended over the north and middle of England, as far south as the Thames Valley and the foot of the Cotswold Hills; but the high moors in Derbyshire and Yorkshire and the tops of the highest mountains in Wales and Scotland rose above its surface. The great Mer de Glace stretched westward over Ireland into the Atlantic, whilst on the east it was continuous across the North Sea with a similar ice sheet which covered Scandinavia and the region of the Baltic, and extended south to the foot of the hills of central Europe, and overspread much of the great central plain. In the extreme south of England, therefore, the conditions differed from those that obtained in the country further north. Although not actually covered with a sheet of ice, yet the more southern counties had been of necessity under the influence of cold, and must have been subjected to the effects produced by rain and snow, by freezing and thawing.

During the succeeding interglacial epoch the climate eventually became temperate and genial, and vegetable and animal life abounded. It is to this stage that most of the Pleistocene river alluvia and cave deposits of England and the adjacent parts of the continent are assigned. The British Islands appear at that time to have been joined to the continent, and the same mammalian fauna then occupied Britain, France and Belgium, which implied similar climatic conditions. As examples of these, it may be sufficient to name the larger mammals, as the cave and grizzly bear, the hyæna, lion, Irish deer, reindeer, hippopotamus, woolly rhinoceros, straight-tusked elephant and mammoth, all of which are now either locally or wholly extinct.

Abundant evidence exists that man was contemporaneous with these mammals in western Europe, as is shown by the presence of his bones alongside of theirs, and of numerous works of his hands, more especially the implements and tools which he had manufactured and employed. To a large extent these consisted of flint, rudely chipped and fashioned. To these implements, and to the men who made them, the well-known term "Palæolithic" is applied. But along with these, other implements have been discovered, made from the bones, horns and teeth of the larger mammals, on some of which animal forms and incidents of the chase have been sculptured both with taste and skill. Up to now, however, no trace of pottery which can without question be referred to Palæolithic men has been found, and no habitations, except the caves and rock shelters which nature provided for them.

One may now consider how far northwards in Britain Palæolithic man and the large mammals, with which he was contemporaneous, have been traced. The exploration of caverns, made by Prof. Boyd Dawkins and other geologists associated with him, has proved that bones of certain of the mammals of this epoch were present in caves in Derbyshire, Yorkshire and North Wales, and that human remains and implements of Palæolithic type have been found along with them in the Robin Hood cave in the Cresswell Crags, and in caverns in North and South Wales.

When Scotland is considered, evidence of the existence of the mammals of this epoch is not so abundant, yet the interglacial beds of that country have yielded remains of mammoth, reindeer, Irish elk, urus, and horse. But notwithstanding the keen scrutiny to which the superficial deposits in Scotland have been subjected by the members of the Geological Survey and others, no traces either of the bones of Palæolithic man or of the work of his hands have been discovered in North Britain. This, indeed, is not much a matter of surprise, for it must be remembered that, subsequent to the genial interglacial epoch, another ice sheet, that of the upper boulder clay, made its appearance, grinding over the surface of the land, wearing away alluvia, and largely obliterating the relics of interglacial times. Hence interglacial beds occur only at intervals and are very fragmentary. Nor in Scotland are there any caves similar in dimensions to those which in England and elsewhere have yielded such abundant traces of Palæolithic man and his mammalian congeners. If Palæolithic man ever did exist in Scotland, and there is no reason why he might not have migrated northward from Yorkshire and Wales, yet one could hardly expect to discover traces of his former presence. In Scotland there are no massive limestones, with extensive caverns, in which man could have sheltered, and in which his relics and remains could have been secure from destruction during the advance of the second ice sheet. It is only in the alluvial deposits of interglacial times that such traces have been preserved, but these deposits, as we have seen, were ploughed out and to a great extent demolished by the later sheet of ice. The shreds that remain, however, are of extreme interest, from the fact that they contain relics of the Pleistocene mammals, with which Palæolithic man was contemporaneous; and there is a bare chance that some day traces of man himself may be encountered in the same deposits.

---

[1] A discourse delivered at the Royal Institution, London, by Sir William Turner, F.R.S.

[1] For the evidence on which these statements are based, consult the "Great Ice Age," by Prof. James Geikie, edition 1894, also his "Classification of European Glacial Deposits," in *Journal of Geology*, vol. iii., April-May 1895.

Geologists have shown that in the regions which were overflowed by the second or minor ice sheet no traces of Palæolithic man, or of the southern mammals with which he was associated, have ever been met with in British superficial alluvia. When found in those regions out of Scotland, they occurred in caves chiefly, and sometimes in the stratified deposits which here and there underlie the upper boulder clay and its accompanying gravels.

So far as Scotland is concerned, one must look for a period subsequent to the melting of the second great ice sheet for evidence of the existence of early man. After its disappearance important fluctuations in temperature and in the relative level of land and sea took place from time to time, so that the climate and the area of land in Scotland differed in some measure from what is known at the present day. Eventually a period of cold again occurred, not so severe, undoubtedly, as in the two preceding glacial epochs, but sufficient to bring into existence considerable district ice sheets and extensive valley-glaciers in the Highlands and Southern Uplands. Scotland at this stage was partially submerged, and many of the Highland glaciers reached the sea and gave origin to icebergs. The submergence slightly exceeded 100 feet, and the marine deposits formed at the time are charged with arctic shells and many erratic blocks and débris of rocks. On a subsequent elevation of the land, the beach formed at this level constituted a terrace, well marked on the coast line in many districts, and now known as the 100-foot beach.

There is good reason to believe that the elevation referred to was of sufficient extent to join Britain again to the continent. It is to this stage that the great timber trees which underlie the old peat bogs of Scotland are referred. The peat with its underlying forest bed passes out to sea, and is overlaid in the Carse lands of the Tay and the Forth by marine deposits, which form another well-marked terrace, the 45 to 50 foot raised beach of geologists.

Thus the elevation of the land that followed after the formation of the 100-foot beach coincided with an amelioration of climate and with the presence of an abundant vegetation, and large mammals, such as the red-deer, the elk, and the *Bos primigenus* roamed through the woods. While these conditions obtained partial submergence again ensued, and the sea rose to fifty feet, or thereabouts, above its present level. Within recent years it has been shown that during this period of partial submergence glaciers reached the sea in certain Highland firths, which would seem to show that the climate was hardly so genial as during the preceding continental condition of the British area, when that region was clothed with great forests. Ere long, however, elevation once more supervened, and the sea retreated to a lower level. Here it paused for some time, and so another well-marked terrace was formed, which is known as the 25 to 30 foot beach.

There is not any evidence of the presence of man in Scotland during the formation of the 100-foot beach or terrace, but one can speak with certainty of his presence there during the period of formation of the later beaches. If one could put oneself into the position of an observer who, at the time of the 40-50 foot submergence, had stood on the rock on which Stirling Castle is now built, instead of the present carse lands growing abundant grass and grain, and studded with towns, villages, and farm-houses, one would have seen a great arm of the sea extending almost if not quite across the country from east to west, and separating the land south of the Forth from that to the north. In this sea great whales and other marine animals disported themselves, and sought for their food. Abundant evidence, that this was the condition at that time in the Carse of Stirling, is furnished by the discovery during the present century of no fewer than twelve skeletons of whalebone whales belonging to the genus Balænoptera or Finner whales, imbedded in the deposit of mud, blue silt and clay which formed the bed of the estuary.[1] This Carse clay, as it is called, is now in places from 45 to 50 feet above the present high-water mark, and is extensively used for the manufacture of bricks and tiles. At a still lower level lies the carse clay of the 25-30 foot terrace. Until the beginning of the present century the clay had been covered by an extensive peat moss, which the proprietors of the land have removed. The question which has now to be considered is—Did man exist in Scotland at the period of the formation of the carse clays and of the two lower sea beaches? There is undoubted evidence that he did.

Along the margin of the 45-50 foot terrace in the neighbourhood of Falkirk one comes upon the shell-mounds and kitchen-middens of Neolithic man. All these occur on or at the base of the bluffs which overlook the carse lands—or, in other words, upon the old sea-coast. Again, in the Carse of Gowrie, a dug-out canoe was seen at the very base of the deposits, and immediately above the buried forest-bed of the Tay Valley. The 25-30 foot beach has been excavated out of the 40-50 foot terrace; it is largely a plain of erosion rather than of accumulation. It is probable, therefore, that many of the relics of man and his contemporaries which have been obtained at certain depths in the 25-30 foot beach may really belong to the period of the 40-50 foot beach. Some of these finds will now be referred to.

In 1819 the bones of a great Fin-whale, estimated about 72 feet long, were exposed in the carse land adjoining the gate leading into the grounds of Airthrey Castle, near Bridge of Allan, about 25 feet above the level of high water of spring tides. Two pieces of stag's horn, through one of which a hole about an inch in diameter had been bored, were found close to the skeleton. In 1824, on the estate of Blair Drummond, in the district of Menteith, a whale's skeleton was exposed, and along with it a fragment of a stag's horn which was said to have a hole in it and to have been like that found along with the Airthrey whale. Mr. Home Drummond also states that a small piece of wood was present in the hole, which fitted it, but on drying, shrunk considerably. Unfortunately these specimens have been lost, and no drawings or more detailed descriptions were ever apparently published, though in some geological and archæological works they have been stated, without any authority, to have been lances or harpoons. Twenty years ago the skeleton of another whale was exposed at Meiklewood, Gargunnock, a few miles to the west of Stirling, and resting upon the front of its skull was a portion of the beam of the antler of a red deer, fashioned into an implement eleven inches long, and six and a half inches in greatest girth; a hole had been bored through the beam, in which was a piece of wood one inch and three-quarters long, apparently the remains of a handle. The implement was truncated at one end, and shaped so that it could have been used as a hammer, whilst the opposite end was smooth and bevelled to a chisel or axe-shaped edge formed by the hard external part of the antler.[2] There can be no doubt that this implement resembled those found alongside of the Airthrey and Blair Drummond whales earlier in the century, and it effectually disposes of the statement that they were lances or harpoons. Dug-out canoes have indeed been found imbedded in the Carse clays at a similar level, so that the people of that day had discovered a means of chasing the whale in the water; one can, however, scarcely conceive it possible to manufacture a horn implement sufficent to penetrate the tough skin and blubber of one of these huge animals, and to hold it in its efforts to escape. It is much more probable that the whale had been stranded at the ebb of the tide in the shallower water near the shore, and that the people had descended from the neighbouring heights, and had used their horn implements, with their chisel-like edges, to flense the carcass of its load of flesh and blubber, and had carried the spoil to their respective habitations. There can be little doubt that these implements rank, along with the dug-out canoes, as the oldest relics made with human hands which have up to this time been found in Scotland, and that they belong to the earliest period of occupation by Neolithic man.

---

[1] See more particularly Mr. Milne Home's "Ancient Water Lines" (Edinburgh, 1882), and "The Raised Beaches of the Forth Valley," by D. B. Morris (Stirling, 1892).

[2] I described this implement in Reports of British Association, 1889, p. 790. It has subsequently been figured in a Report by Dr. Munro in the *Proceedings of the Society of Antiquaries*, 1896.

After the oscillations in the relative level of land and sea had ceased, and the beach found at the present day had been formed, evidence of the presence of Neolithic man and of mammals, both wild and domesticated, such as now exist in Scotland, becomes greatly multiplied.

Shallow caves or rock shelters situated in the cliff which bounds the esplanade at Oban Bay, which, after being closed for centuries by a landslide from the adjacent height, had recently been quarried into in obtaining stone for building purposes, were described by the lecturer.[1] The caves were as a rule 100 yards inland, and about 30 feet or more above the present high-water mark. They had, no doubt, been formed by the action of the waves at the period of formation of the 25-30 foot beach, for the floor of one of the caves was covered by a layer of gravel and pebbles, which had obviously been washed there when the sea had had access to it.

In these caves, bones representing fifteen human skeletons, men, women, and children were found; also bones of the *Bos longifrons*, red and roe deer, pig, dog, goat, badger, and otter, shells of edible molluscs, bones of fish, and claws of crabs; flint scrapers, hammer stones, implements of bone and horn fashioned into the form of pins, borers and chisel-shaped instruments. In one cave several harpoons or fish spears made of the horns of deer were obtained; similar in form to those found in the Victoria Cave, Settle, in Kent's Cavern, and in the grotto of La Madelaine, France, which in some of these instances have been associated with Palæolithic objects.

An account was then given of the construction and contents of the chambered horned cairns in Caithness and the north-west of Scotland, which have been so carefully investigated and described by Dr. Joseph Anderson ("Scotland in Pagan Times," Edinburgh, 1886). The presence of incinerated bones and of unburnt skeletons showed the cairns to have been places of interment, whilst flint flakes and scrapers, bone and polished stone implements, and shallow vessels of coarse clay, associated them with Neolithic man, obviously the same race as the builders of the English long barrows.

Stone abounds in Scotland, and the polished stone implements which have been found in every county, in the soil and near the surface of the ground, are often of large size, and beautifully ground and polished. Flint, on the other hand, is confined to a few localities, as the island of Mull and limited areas in the counties of Banff and Aberdeen. The nodules are as a rule small in size, and though adapted for the manufacture of arrow-heads and scrapers, flint does not seem to have attained the same importance in Scotland as the raw material provided by nature for the manufacture of articles used by Neolithic man, as was the case in England and Ireland.

Although there is ample evidence of the nature of the implements and weapons manufactured by Neolithic man, and of his methods of interment in rock shelters and chambered cairns, no traces of built dwellings which can be ascribed to the people of this period have been discovered. Doubtless their habitations were constructed of loose stones and turf, and sun-dried clay, or of the skins of animals killed in the chase spread over the branches of trees, which, from their fragile and destructible character, have not been preserved.

In the course of time stone and bone, readily procurable, and which are directly provided by nature for the use of man, gave place to materials which require for their manufacture considerable skill and knowledge. The introduction of bronze as a substance out of which useful articles could be made, marked an important step in human development, and could only take place after men had learnt by observation the ores of copper and tin, and by experiment the methods of extracting the metals from them, and the proportions in which they should be combined in the alloy in order to secure the necessary hardness. So far as Scotland is concerned, bronze must have been introduced from without; its manufacture could not have been of indigenous development, as the ores of tin and copper do not occur in North Britain. Doubtless it came from the southern part of our island, and was extensively employed in South Britain long before it became substituted in the north for the more primitive materials.

There is abundant information that Scotland had a Bronze Age. Swords, spears, bucklers, bracelets, rings, fish hooks, axes, chisels, sickles and other implements made of this metal have been found in considerable numbers. These objects occur sometimes singly, at others in collections or hoards in peat mosses, or even at the bottom of lochs and rivers, or buried in the soil as if they had been placed there with a view to concealment, and then, through the death or removal of their owners, had been lost sight of. In many instances these weapons and implements are elegant in design, show great mechanical ability in their construction, and are ornamented with much taste and skill. Instances also are not uncommon in which objects of bronze are found in the sepulchres of the period.

In the study of the Bronze Age in Scotland a want is experienced similar to that felt in a review of the Neolithic period. There are no buildings which can be distinctly regarded as dwelling-places for the men of this time. With them, however, as in the Polished Stone Age, there is evidence of the mode in which they disposed of their dead friends and relatives. Interments which there are good grounds for associating with these people, have been exposed in the formation of roads and railways, and in agricultural operations. Where the surface of the ground has not been cultivated or otherwise disturbed, in almost every county tumuli, mounds, hillocks and cairns occur, the exploration of which has in many cases yielded interesting results. In no instance, however, have chambered cairns, divided into compartments, and possessing an entrance passage, been found associated with articles made of bronze. The sepulchral arrangements of the period possessed a greater simplicity than is shown in the chambered cairn.

The interments in the Bronze Age were sometimes that of a single individual in a knoll or mound, or under a cairn artificially constructed, and now overgrown with grass, heather and whin bushes, or, as is not uncommon, in a collection of sand or gravel near the sea shore, or on a river bank, or in the moraine of some long-vanished glacier. At other times, in similar localities, two to six interments had been made as if in a family burying ground. At others the interments were much more numerous, and represented doubtless the cemetery of a tribe or clan; one of the best known of these was observed some years ago at Law Park, near St. Andrews, in which about twenty interments were recognised. In another at Alloa, twenty-two separate interments were exposed. Quite recently, immediately to the east of Edinburgh, in the districts now known as Inveresk and Musselburgh, not less than fifty interments of this period have been brought to light, in connection with building operations, which implies that then, as now, this part of the country was settled and had a considerable population.

Two very distinct types of interment prevailed, viz. Cremation, with or without cinerary urns; and Inhumation, the unburnt body being enclosed in a stone cist or coffin. From an analysis of 144 localities in Scotland of burials which may be associated with the Bronze Age,[1] and which included about 400 distinct interments, it would appear that in fifty-one of these localities the bodies had all been cremated; in sixty they had been buried in stone cists; in fifteen the same mound or cemetery furnished examples of both kinds of sepulchre, and in the rest the kind of interment was not precisely recorded. These diversities did not express tribal differences, but seemed to have prevailed generally throughout Scotland. Both cremation and inhumation are found in counties so remote from each other as Sutherland in the north and Wigton in the south, in Fife and the Lothians on the east, and in Argyll and the distant Hebrides in the west, as well as in the intermediate districts.

The cremation had been effected by wood fires, for in many localities charcoal has been found in considerable quantity at the place of interment. The heat generated was sufficient to reduce the body to ashes, and to burn the organic matter out of the bones, which fell into greyish-white fragments, often curiously cracked and contorted, which were not very friable. They were then collected and usually placed in an urn of a form and size which we now call Cinerary. When a bank of sand or gravel was convenient, a hole three or four feet deep was made and the urn lodged in it. Sometimes the urn stood erect, and a flat stone was placed across the mouth before the hole was filled in with sand and earth; at others a bed of compacted earth, or of small stones, or of a flat stone, was made at the bottom of the hole, and the urn, with its contents, was inverted. In some cases the urn was protected by loose stones arranged around it. In obviously exceptional instances, it may be perhaps of a tribal chieftain, a small stone cist was built to enclose the urn, and even a cairn of stones was piled above and around to protect it and to mark the spot.

---

[1] For a detailed description, see papers by Dr. Joseph Anderson and the author in *Proc. Scot. Soc. Antiquaries*, 1895.

[1] Most of these are recorded in the "Archæologica Scotica," the *Proceedings* of the Scottish Society of Antiquaries, and Dr. Joseph Anderson's "Scotland in Pagan Times"; whilst others, in the author's note books, have not yet been published.

Cremated interments not contained in urns have been recorded in a few instances, and in them the surrounding sand or gravel has usually been discoloured, from the blackened remains and charcoal having to some extent become diffused through it.

The largest examples of cinerary urns were from 12 to 16 inches in height, with a flat narrow bottom, and 10 to 12 inches wide at the mouth. About one-third the distance below the mouth the urn swelled out to its widest diameter, and was surrounded by one or two mouldings, between which and the mouth the outer surface was often decorated with lines which ran horizontally, or vertically, or obliquely; sometimes they intersected, and formed a chevron or a diamond-shaped pattern. Below the mouldings, the surface was without pattern, though sometimes raised into an additional simple circular moulding.

When the inhumation of an unburnt body was decided on, a rude cist or coffin, formed of undressed flattened stones, was built for its reception. As a rule, the sides and ends of the cist were formed each of a single slab of sandstone, schist, gneiss, granite or other stones provided by the rock in the neighbourhood; but in some instances of a stone of a different character from the adjoining rocks, and obviously brought from a distance. The stones were set on edge and supported a great slab, which, being laid horizontally, formed the lid or cover of the cist, and which was much thicker and heavier than the side and end stones; sometimes, as if for additional protection, a second massive slab was placed on the top of the proper cover. The floor of the cist was formed, when the earth was shallow, of the native rock, and at other times of compacted earth, or a layer of pebbles, or of flat stones. Usually the stone walls and the cover of the cist were simply in apposition, but sometimes they were cemented together with clay. In some cists, exposed a few years ago on the farm of Cousland, near Dalkeith, the peculiarity was observed of the cist being divided in its long direction into two compartments by a stone slab down the middle.

The cists were oblong, the length exceeding the breadth, and although they varied in size, those for adults being larger than for children, they were always shorter than would have been required for a body to be extended at full length. As the end stones were usually set within the extremities of the side stones, the internal measurement of length was some inches less than the external. The average dimensions may be given for the interior about 4 feet in length, 2 feet in breadth, and 2 feet in depth. The cover slab was much larger both in length and breadth, as it overlapped both the sides and ends.

These cists remind one, in their general form and plan, but on a much smaller scale, both as regards the size of the enclosed space and the magnitude of the stones, of the dolmens so frequent in Brittany. As survivals in modern times, we may point to the empty stone boxes, on the cover stone of which an inscription is incised, to be seen in so many country churchyards, built on the ground superficial to the pit in which the body in its wooden coffin has been inhumed.

Owing to the shortness of the cist the body could not be extended at full length, but was laid upon its side, with the elbows bent, so that the hands were close to the face; the hips and knee joints were also bent so that the knees were in front of the body.

Usually only a single skeleton has been found in a cist, either a man or a woman as the case may be. Sometimes two skeletons have been seen, at times a man's and a woman's, doubtless husband and wife; in others the second skeleton has been that of a child. Sometimes the cist was below the average in size, and contained only the skeleton of a child or young person. Such examples throw light upon the family relations of the people of this period. They show that they desired to preserve the associations of kinsfolk even after death; and when the cist contained the remains only of a child it was constructed with the same care as if it had been the tomb of a chief.

When cremated bodies are found associated with stone cists in the same cemetery, the cinerary urns in which the ashes were customarily deposited lie outside the cists, and in quite independent excavations in the soil, but in such close proximity as to show that they belonged to the same period. In two instances short cists have been opened, in which, alongside of the skeleton of an unburnt body, were cremated human bones, not contained in a cinerary urn, but scattered on the floor of the cist, which conclusively prove that both cremation and inhumation were sometimes in practice at the same interment.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. CHARLES E. GREEN, President of the Board of Trustees of Princeton University, died suddenly on December 24.

LAFAYETTE COLLEGE, at Easton, Pennsylvania, suffered serious loss by fire a few days ago for the second time in its history. Pardee Hall, with its valuable collections, was nearly destroyed, and the library was much injured.

Science states that bills have been again introduced into both Houses of Congress to establish the University of the United States. Such a bill was introduced by Senator Edmunds in 1890 and referred to a select committee, which reported unanimously in its favour. The standing committee since appointed has also reported unanimously in its favour, and it is said that the bill will probably be passed during the present session.

AMONG recent appointments are:—Dr. S. Fuchs to be associate professor of physiology at the University at Jena; Prof. Waldemar Lindgren, of the U.S. Geological Survey, to be professor of metallurgy and mining engineering in Stanford University; Mr. Edgar R. Cumings, of Cornell University, to be instructor in geology in the University of Indiana; Dr. W. Ophüls to be professor of pathological anatomy in the University of Missouri.

AN additional chair of Chemistry has been founded and endowed in the McGill University, Montreal, by Mr. W. C. McDonald, who recently erected a new chemical building at a cost of 240,000 dols. The same donor has provided an additional endowment of 50,000 dols. for the faculty of Law, to the deanship of which faculty, with the chair of Roman Law, Mr. F. P. Walton, of the Scotch Bar, was recently appointed. Mr. McDonald has, moreover, supplemented the existing endowments associated with his name by a further gift of 200,000 dols. to provide for any deficiency in income that may result from the fall in the rate of interest on investments.

SCIENTIFIC SERIALS.

Symons's Monthly Meteorological Magazine, December, 1897.—A wet day in a wet district. A remarkably heavy rainfall occurred in the Lake district on November 12. At Skelwith Fold (Lancashire) it amounted to 6·03 inches, or 7·5 per cent. of the annual mean; at Skelwith Bridge (Westmoreland) 6·35 inches were measured, or 7·8 per cent., and at Leathwaite (Cumberland) 8·03 inches, or 6·1 per cent. of the annual mean. There was no thunderstorm, but a continuous pelting rain nearly throughout the twenty-four hours. Naturally, much damage was caused by floods.—Temperature variations in November. An observer at Cheltenham draws attention to some remarkable changes during November 14 to 20, the greatest of which was a fall of 21°·4 between the 18th and 19th. In the neighbourhood of London the greatest difference between any two consecutive readings during November was 19°·6. Mr. Symons points out that nearly similar differences also occurred in 1866 and 1893.—The same number also contains some useful particulars, with illustrations, respecting Richard's instruments for use with kites or balloons. Pressure, humidity, and temperature are simultaneously recorded on a single sheet of paper; the total weight of the instrument is only 36 ounces.

Wiedemann's Annalen der Physik und Chemie, No. 12.—Origin of contact electricity, by C. Christiansen. The gas surrounding a jet of zinc, lead, or tin, amalgam has a marked influence upon its uninterrupted length. Air, oxygen, and sulphurous acid have the effect of retarding the breaking up of the jet, owing to contact electrification. The author measures the length of the continuous jet by making it part of a circuit containing a galvanometer, the steadiness of the needle denoting the continuity of the jet. He finds that air or oxygen have no effect when quite dry.—Temperature of the electrodes of mercury arc lamps, by L. Arons. In the arc lamp with mercury electrodes, devised by Arons, the anode is the hotter, and gradually distils over into the kathode, which is flickering and turbulent. Mercury is condensed on the walls of the vacuum tube, which are easily obscured.—Deflection of kathode rays, by W. Kaufmann and E. Aschkinass. The authors determined the deflection produced in kathode rays by a narrow field due to condenser plates mounted in a tube crossing the vacuum tube at right angles. They found that the amount of deflection observed is strictly in accordance with the projection hypothesis of kathode rays as against the German wave hypothesis.—Magnetic deflection of kathode rays, by W. Kaufmann. The above result led the author to redetermine the ratio e/m of the charge of the projected particles to its mass, by a close study of the magnetic field deflecting the ray. It was found to be $1{\cdot}77 \times 10^7$ instead of 10^7.—Kathode rays, by E. Wiedemann and G. C. Schmidt. There are two distinct kinds of kathode rays, which proceed from a point in the form of a solid cone and of a hollow cone respectively, producing on the wall of the tube a patch or a ring. The authors studied these two species under the simplest conditions. They placed a knob, forming the terminal of a Lecher secondary wire, against an exhausted glass sphere without electrodes. A hollow cone proceeded from a point in the sphere next to the knob, whose angle varied with the exhaustion, the size of the sphere, and the curvature of the electrode, increasing as they increased.—Electric observations by balloon, by R. Börnstein. The balloon offers the best means of determining the true potential at any point in the atmosphere, but the charge of the balloon itself is a source of error. This may be eliminated by employing three collectors for three successive points below the balloon, and only about 2 m. distant from each other. If the decrease of potential is uniform, the charge of the balloon is zero. Otherwise, the charge is easily calculated from the observed decrements.—Thermodynamics of luminescence, by K. Wesendonck. A luminescent body is capable of imparting heat to a body warmer than itself. This does not contradict the second law of thermodynamics, as luminescence is not ordinary thermal radiation.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 16, 1897.—"The Comparative Chemistry of the Suprarenal Capsules." By B. Moore, M.A., and Swale Vincent, M.B.

In this paper it is shown that the "paired bodies" of Elasmobranch fishes contain the same chromogen as the medulla of the suprarenal capsules of mammals. In previous papers Vincent had shown not only that the "paired bodies" bear a close resemblance histologically to mammalian medulla, but that they contain a substance which constricts arterioles and raises blood pressure in a similar manner to mammalian medulla.

From the chemical point of view Moore had further shown that this active substance is closely associated with a chromogen also found only in the suprarenal medulla. The active material and chromogen are not, however, identical, for the activity may be destroyed without destroying the chromogen by allowing the material to stand for seven to ten days in strong alcohol. Moore hence supposes that the active material has a complex molecule which is decomposed by the alcohol, and that the chromogenic properties are attached to a group in this molecule which is unattacked in the decomposition.

The colour reactions of the chromogen show that it contains an ortho-dihydroxy-benzene nucleus; thus, it gives a deep green coloration with ferric chloride, and reduces silver nitrate in the cold. Besides these tests, it gives a rose-red colour with alkalis and free halogens and other reactions, which show that it is a strong reducing agent.

Using these colour reactions as tests the chromogen was sought for in extracts of the paired bodies of Elasmobranchs (*Scyllium canicula*), and was found to be present in abundance.

It was also shown that no chromogen is present in the inter-renal of Elasmobranchs, which, according to Vincent, corresponds to the cortex of the suprarenal of mammals.

Thus, additional evidence is furnished that the paired bodies correspond to mammalian medulla, while the inter-renal does not resemble medulla and is probably cortex, as suggested by Vincent.

"On a Method of determining the Reactions at the Points of Support of Continuous Beams." By George Wilson, M.Sc., Demonstrator in Engineering in the Whitworth Laboratory of the Owens College, Manchester.

The solution given in this paper differs from those of Bresse, Clapeyron, and Heppel, insomuch that the reactions at the points of support are considered as the unknown quantities to be determined, instead of the bending moments over the piers.

It is shown that by considering the continuous beam as a beam supported at each end and under the action of the given loading acting downwards, and the intermediate supports considered as unknown concentrated loads acting upwards, and equating the deflection at any intermediate point of support caused by the former loading to that caused by the several intermediate reactions treated as concentrated loads, the following series of equations is obtained, viz.:—

$$\begin{aligned} N_1 &= R_1 n_1' + R_2 n_1'' + R_3 n_1''' + \ldots \\ N_2 &= R_1 n_2' + R_2 n_2'' + R_3 n_2''' + \ldots \\ &\text{\&c.} \qquad\qquad \text{\&c.} \end{aligned}$$

Where R with the correct suffix is the reaction at any intermediate point of support, and N and n with their suffixes are quantities depending on the dimensions of the beam and the loading.

The quantities n are constant and need only be determined once, whilst the value of N changes with the position and magnitude of the live load. A method of determining these constants when the cross section of the beam is variable, is given; when the cross section is uniform, the equations can be written down at once.

The elevation or depression of the supports from any cause affects the values of R, the alterations in which can be determined by means of the above equations when the amount of the elevation or depression is known.

An example is appended to show the application of the method.

Geological Society, December 15, 1897.—Dr. Henry Hicks, F.R.S., President, in the chair.—On the Pyromerides of Boulay Bay, Jersey, by John Parkinson. After briefly noticing the literature of the subject, the author described the altered rhyolites of Boulay Bay. One variety, the commonest, is of a dark red colour, showing flow-structure; another is porphyritic; a third, near the centre of the Bay, has a pale greenish matrix enclosing fragments, which, however, are due to flow-brecciation. Large pyromerides occur in two localities: in the more interesting, that north of the jetty, the structure of the rock indicates either a very peculiar magmatic differentiation *in situ* or (more probably) the mixture of two magmas differing in their stage of consolidation. From study of a series of specimens of the pyromeridal rock, the author arrived at the following conclusions: (1) The rock shows marked flow-structure and at times bands which indicate a slight difference in its composition, the latter tending to assume a moniliform outline. In such the microscopic structure corresponds with that of the pyromerides, and exhibits traces of radial crystallisation. (2) These afford a passage into somewhat oval pyromerides, with rather tapering ends and irregularly mammillated surfaces. (3) From these sometimes a single one seems to be thrown off, while lines of pyromerides or little lumps of similar material are scattered about the matrix. (4) Many of the pyromerides are solid throughout; others have a central cavity filled with quartz.—On the exploration of Ty Newydd Cave near Tremeirchion, North Wales, by the Rev. G. C. H. Pollen. In November 1896 a Committee was formed, consisting of Dr. H. Hicks, Dr. H. Woodward, and the author, for the purpose of exploring this cavern, which is situated in the same ravine on the east side of the Vale of Clwyd as the well-known caverns of Ffynnon Beuno and Cae Gwyn, explored about twelve years ago by Dr. H. Hicks and Mr. E. B. Luxmoore. Grants have been made by the Royal Society and by the Government Grant Committee for the purpose of carrying on the explorations; and though a considerable time must elapse before the work is completed, the results already obtained are of importance. The cavern had been in part broken into by quarrying operations, but the chambers and tunnels were completely filled up with more or less stratified deposits, and had remained entirely untouched. Although the ground above the cavern is strewn over with drift and erratics from the north and from the central areas of Wales, not a fragment of anything but immediately local material has been discovered in the cavern itself, showing clearly that the deposits in the cavern had been carried in by water before the northern and western ice had reached this area. The work has been carried on almost continuously throughout the year, and most of the material has been removed for a distance of over 60 feet from the entrance. The height of the cavern above sea-level is 420 feet, or about 20 feet above the floor of the Cae Gwyn Cave. The following points appear to the author to be now fully established: (1) The material in the Ty Newydd Cave, as in the lower parts of those of Ffynnon Beuno and Cae Gwyn, is of purely local origin. Of this he can speak with confidence, as the question was before him from the beginning and the gravels were examined with minute care for erratics. (2) This local deposit is of earlier date than the boulder clay with western and northern drift. This was proved by the finding of granite- and felsite-boulders abundantly at higher levels and over the cave, and in one case filling the upper part of one of the fissures communicating from above with the cavern. (3) The occurrence of the tooth of a large mammal (*Rhinoceros*) in the lower part of the cave shows that the animal was contemporary with, or of earlier date than the infilling of the cavern by the local drift.

Chemical Society, December 15, 1897.—Prof. Dewar, President, in the chair.—Prof. F. R. Japp delivered the Kekulé Memorial Lecture (see p. 180)—December 16, 1897.—Prof. Dewar, President, in the chair.—The following papers were read:—Stereochemistry of unsaturated compounds. Part i. Esterification of substituted acrylic acids, by J. J. Sudborough and L. L. Lloyd. The authors have made experiments on the esterification of many cinnamic acids and other derivatives of acrylic acid; the acids were boiled under fixed conditions with methylic alcohol solutions of hydrogen chloride, and the quantity of methylic salt formed was subsequently determined. Several rules governing the speed and course of esterification are formulated.—Formation and hydrolysis of esters, by J. J. Sudborough and M. E. Feilmann. The authors conclude that in the conversion of an acid into its ester by the action of an alcohol, either with or without hydrogen chloride, the rate of esterification is determined by two factors, namely (1) the configuration of the acid or the close proximity of substituting groups to the carboxyl group, and (2) the strength of the acid as determined by its affinity constant. The same two factors operate in determining the rate of hydrolysis of the ester.—A new method of determining freezing points in very dilute solution, by M. Wildermann.—A possible basis of generalisation of isomeric changes in organic compounds, by A. Lapworth. The author points out that many isomeric changes, hitherto regarded as of dissimilar types, may be formulated as special cases of a general form, expressible by the reversible equation $R_\alpha M . R_\beta : R_\gamma \rightleftarrows R_\alpha : R_\beta . R_\gamma M$; a labile group M moves from an α to a γ position, the necessary rearrangement of single and double bindings taking place between the three atoms, R_α, R_β and R_γ. By the aid of this general formula and its extended forms the author is able to explain a large number of cases of desmotropy, tautomerism and isomeric change.

DUBLIN.

Royal Dublin Society, December 22, 1897.—Prof. G. F. Fitzgerald, F.R.S., in the chair.—Prof. Thomas Preston read a paper on the radiation of light in a magnetic field. The author described how he had been led to apply photography to the study of the effect (recently discovered by Prof. Zeeman) produced by a strong magnetic field on the radiation from a source of light placed in it. The photographs were projected on a screen, and they rendered all the effects described by Prof. Zeeman clearly visible to a large audience (see p. 173).—Prof. J. Joly, F.R.S., then read a note on a theory of sun-spots. If at some level in the photosphere the temperature falls below the critical temperature of the elements present, and the pressure is sufficient, a precipitation of liquid will result; and it is suggested such a precipitated flood of liquid matter, supported on gaseous matter of higher density, would give rise to the appearances presented by a sun-spot. If the liquid is opaque, it will look darker than the surrounding photosphere. The reflection of the photosphere at the edge and the inrush of gaseous matter over the cooler area will, it is believed, explain the appearance of the penumbra. The re-evaporation of the liquid constitutes the disappearance of the spot. On this view the sun-spot con[illegible] the first beginning of a change of state in the sun visible

PARIS.

Academy of Sciences, December 20, 1897.—M. A. Chatin in the chair.—The Secretary informed the Academy of the loss it had sustained through the recent death of M. Brioschi, of Milan.—Observations relative to the coffins of Voltaire and of Rousseau, opened December 18, 1897, by M. Berthelot.—Determination of the absolute coordinates of the stars, and also of the latitude, by means of meridian instruments. General method for the solution of these problems, by M. Lœwy.—On the periods of double integrals of algebraic functions, by M. Emile Picard.—Comparison of the thermogenetic or dynamogenetic power of simple food-stuffs with their nutritive value, by M. A. Chauveau. A considerable difference exists between the isoenergetic and isotrophic weights of sugar and fat in the case of a working subject. The isoglycogenetic and isotrophic powers are practically identical.—On those cases of the problem of three bodies (and of *n* bodies) in which two of them collide at the end of a finite time, by M. Painlevé.—On a special method of circumzenithal observations, by M. Ch. Rouget. A further study of the method described in a previous note.—On a particular conjugate net of certain surfaces derived from surfaces of the second order, by M. S. Mangeot.—On Taylor's series, by M. Eug. Fabry.—On the isothermal and adiabatic transformations of true gases; determination of the ratio of the two specific heats, by M. A. Leduc.—On an apparatus permitting of the separation of simple radiations in close proximity, by M. Maurice Hamy. The method is based upon the principle of interference.—Ebullioscopy of some salts in ethereal solution, by M. R. Lespieau. Results are given for uranyl nitrate and the chlorides of mercury, iron, zinc, and antimony.—On cerium, by M. Boudouard. A reply to criticisms on a former paper by the author.—On the duration of the phosphorescent power of sulphide of strontium, by M. José Rodriguez Mourelo. Experiments on sulphide of strontium prepared by different methods show that those specimens which exhibit the greatest intensity of phosphorescence are also those in which the property is most quickly developed and is preserved for the longest time.—Volumetric estimation of antimony, by M. H. Causse. The new method proposed is an iodometric one, depending upon the liberation of iodine from iodic acid by antimonious oxide.—Difference between nitroso-substitution derivatives according as the NO group is directly connected with carbon or with nitrogen, by MM. Camille Matignon and Deligny. A thermochemical paper.—A colour reaction of ordinary aldehyde, by M. Louis Simon. A blue colour is produced on the addition of solutions of trimethylamine and of nitro-prussiate of sodium. The reaction is not given by other aldehydes.—Action of piperidine upon carbonic ethers of phenols; formation of aromatic urethanes, by MM. Cazeneuve and Moreau.—On two Lepidoptera destructive to the sugar-cane in the Mascarene Isles, by M. Edmond Bordage. The author endeavours to clear up the confusion which has arisen as to the history and nomenclature of two species, the larvæ of which are known as "borers."—On the nuclear value of the *central body* of bacteria, by MM. J. Kunstler and P. Busquet.—On extra-liberian cribriform tissue and extra-ligneous vascular tissue, by M. E. Perrot.—On potato rot, by M. E. Roze. An account of the nature and causes of the various changes to which the tubers are liable after gathering.—The composition of oat, wheat, and rye straw, by M. Balland. The results of analyses show no difference between the three varieties of straw, which contain only trifling quantities of nutritive material. Short and leafy straw is to be preferred for the food of horses, and long straw for their litter.—On the presence of beds containing *Planorbis pseudo-ammonius* and *Bulimus Hopei* in the neighbourhood of Sabarrat and Mirepoix (Ariège), by M. G. Vasseur.—Influence of sub-nitrate of bismuth upon the "hardening" of cider, by MM. Leon Dufour and Daniel. The presence of the salt greatly retards the development of acidity. Its addition is recommended in the proportion of 10 grams per hectolitre (0·01 per cent.).—On the estimation of the acidity of urine, by M. H. Joulie. Advantages are claimed for the use of a standard solution of saccharate of lime. No indicator is required, the end-point being shown by the production of a precipitate of phosphate of calcium when the free acid and acid phosphate of sodium have been neutralised.—On the fermentation of cellulose, by M. V. Omelianski. A quantitative study of the action of the ferment described in a previous communication. The products of the decompositions are hydrogen, carbon dioxide, and a large proportion of fatty acids.—Muscular atrophy experimentally produced by pyocyanic intoxination, by MM. Charrin and H. Claude.—On tubercular sclerosis of the pancreas, by M. Paul Carnot.

December 27.—M. A. Chatin in the chair.—In an obituary notice of M. F. Brioschi, whose recent death was announced at the previous meeting, M. Hermite gave a brief account of the work of that distinguished mathematician.—A special method for the absolute determination of declinations and of latitude, by M. Lœwy. A further development of the subject of the author's previous communication.—The centrosomes in vegetable cells, by M. L. Guignard.—On phthalic green. Constitution, by MM. A. Haller and A. Guyot. The colouring matter previously described is to be considered as a substitution derivative of malachite green. The results obtained by Fischer are explained by the presence of impurities in the materials used by him.—Observation of the shower of Orionids, December 12-14, at Athens, by M. D. Eginitis.—On the existence of integrals in orthoic systems, by M. Riquier.—On surfaces applicable to a surface of revolution, by M. A. Pellet.—On linear functional equations, by M. Lémeray.—On a spring ergograph, by MM. A. Binet and N. Vaschilde. Several advantages are claimed for the use of a spring, instead of a weight, in this instrument.—Conductivity of radio-conductors or discontinued electrical conductivity. Resemblance to nervous conductivity, by M. Edouard Branly.—Magnetic properties of tempered steels, by Mme. Sklodowska Curie.—On the polarisation of the light emitted by a sodium flame placed in a magnetic field, by M. A. Cotton.—On the preparation of alloys of beryllium. Alloys of beryllium and copper, by M. P. Lebeau. The alloys are obtained by heating, in an electric furnace, an intimate mixture of oxide of beryllium, oxide of copper, and charcoal.—On the impurities of aluminium and of its alloys, by M. Ed. Defacoz. The author seeks to determine the form in which the foreign elements (silicon, iron, and copper) exist in the metal.—On a double carbonate of sodium and protoxide of chromium, by M. G. Baugé. The new salt results from the action of a solution of sodium carbonate upon chromous acetate in an atmosphere of carbon dioxide. It crystallises with either one or ten molecules of water and is a powerful reducing agent, decomposing water at 100° C. with evolution of hydrogen.—On the atomic weight of cerium, by MM. Wyrouboff and A. Verneuil. A rejoinder to M. Boudouard's criticism.—On the use of carbide of calcium in the preparation of absolute alcohol, by M. P. Yvon. Pure alcohol is without action upon calcium carbide, but the presence of even traces of water leads to the evolution of acetylene and formation of calcium hydrate. It is therefore possible by one, or at most two, distillations to prepare absolute alcohol from spirit of 90 per cent. strength.—On the aromatic diurethanes of piperazine, by MM. P. Cazeneuve and Moreau.—On a acetylfurfurane and its presence in wood-tar, by M. L. Bouveault.—On the behaviour, on distillation, of a mixture of pyridine with propionic, acetic, and formic acids. The author has studied the progress of fractionation in the case of mixtures of a volatile acid with a feeble base. In the case of pyridine and formic acid the former begins to distil over in a nearly pure state, although its boiling point is 14° higher than that of formic acid.—On crystalline minerals formed under the influence of volatile agents at the expense of the andesites of the island of Thera (Santorin), by M. A. Lacroix.—The theory of the sense of orientation in animals, by M. G. Reynaud.—On the generation of leucocytes in the peritoneum, by M. J. J. Andeer.

DIARY OF SOCIETIES.

A SYSTEM OF MEDICINE.

A System of Medicine. By many Writers. Edited by Thos. Clifford Allbutt, M.A., M.D., F.R.C.P., &c., Regius Professor of Physic in the University of Cambridge. Vol. iii. Pp. xi + 1001. Illustrations 23. Charts iv. Plate i. Vol. iv. Pp. xii + 880. Illustrations 31. Plate i. (London: Macmillan and Co., Ltd., 1897.)

THE works before us are the third and fourth volumes of Prof. Allbutt's "System of Medicine," the first and second volumes of which have been already reviewed in these columns.

Vol. iii. begins with a consideration of the General Diseases of Obscure Causation. The subject is introduced by an article on Acute Rheumatism, or Rheumatic Fever, which is contributed by Dr. Church. This article contains a mass of clinical information drawn from a rich bibliography, and supplemented by the author's own ample experience at St. Bartholomew's; as an instance of the latter, we may mention a chart of 1998 cases of rheumatic fever arranged in months according to the time of onset of the disease. Acute Rheumatism in children is dealt with by Dr. Cheadle, and forms a valuable addition to the above article. The very various manifestations of acute rheumatism in children are described, and the relative sudsidiary importance of the arthritic phenomena is emphasised. Rest and full alkaline treatment are, according to the author, the most valuable therapeutic measures in diminishing the frequency of the occurrence of cardiac inflammation.

The articles on Chronic Rheumatism, Gonorrhœal Rheumatism, and Muscular Rheumatism are from the pen of Dr. A. E. Garrod. The essay on Rheumatoid Arthritis is contributed by Dr. Kent Spender, of the Royal Mineral Water Hospital, Bath; unfortunately, before its completion he had to relinquish the task. The revision, however, fell into fortunate hands, and was undertaken by Dr. A. E. Garrod, who entirely contributes the section on treatment. Rheumatoid arthritis in children forms the subject of a special essay by Dr. Still. The monograph on Rickets is written by Dr. Cheadle, and includes a full description of the disease, an account of its pathology and treatment, and of its modifications and concurrent disorders. Mr. Bowlby contributes three succinct articles on Mollities Ossium, Acromegaly, and Hypertrophic Pulmonary Osteo-arthropathy.

All will agree that the essay on Gout could not have fallen into better hands, coming as it does from the pen of Sir William Roberts. The author expresses the views so clearly enunciated by him in the Croonian Lectures for 1892, with regard to the existence and decomposition of the so-called quadri-urates. The relative merits of the mechanical and chemical theories of the production of the symptoms of gout are carefully examined. The monograph concludes with a consideration of the general and local treatment of gout. Dr. Saunby contributes the article on Diabetes Mellitus; the late Dr. Ralfe the one on Diabetes Insipidus. This part of the volume concludes with an essay on Lardaceous Disease by Dr. Howship Dickinson.

The second division of the work is devoted to diseases of Alimentation and Excretion. Two essays on the general pathology of Digestion and Secretion introduce the subject. In the former, Drs. Ralfe and Soltau Fenwick give an account of what may perhaps not inappropriately be termed the clinical chemistry of digestion, and describe the more recent methods for the qualitative and quantitative determination of the various constituents—normal and pathological—of the digestive juices, more especially, of course, of the gastric juice. It is to be wished that the value of exact chemical examination of the gastric contents after test meals should be more recognised in this country. The general Pathology of Secretion is the subject of a short essay by Dr. Rose Bradford. The pathological modifications, both in quality and quantity, of external and internal secretions are considered. Shock and Collapse is treated in an original manner by Dr. Cobbet; Diseases of the Mouth by Dr. Wills, and Diseases of the Œsophagus by Dr. Rolleston.

The Diseases of the Stomach are treated by several authors. Among the monographs composing this subsection of the work may be mentioned the essays on Dyspepsia and Gastritis, by Dr. Lauder Brunton. These articles contain a mass of valuable clinical information, and many useful hints for the treatment of these disorders. They are written in that clear and lucid style which is characteristic of their author. Dr. Stocker contributes a short account of Sea-sickness. He divides the treatment of this most unpleasant disorder into preventive and remedial. Under the former head he advises light diet and purgation before starting. He regards the beneficial action of the bromides as most probably due to the anæsthetic action which they exert on the pharynx and larynx, and suggests that they would probably be as efficacious if given as gargles. The Editor writes an account of Mountain-Sickness. He adopts the view that the symptoms are due to the diminished oxygen tension obtaining at high altitudes. Prof. Allbutt further contributes the essays on Neuroses of the Stomach and Gastrectasis. In the former article the author gives an account of the recent researches of Pawlow upon the nervous mechanisms influencing gastric secretion. He then passes to the symptoms of the many varieties of gastric neuroses. Motor Disorders of the stomach are dealt with, and the article concludes with an account of the neuroses of the other abdominal viscera. The article on Gastrectasis comprises a discussion of the ætiology, varieties, diagnosis and treatment of this disease.

The essay on Ulcer of the Stomach is written by Dr. Dreschfield. The author first gives a brief account of the history of this affection, he then passes on to the ætiology, considering the *rôle* played in its production by sex, age, race, climate, occupation, &c. The discussion of symptomatology is very full, and includes a mention of Acetonuria and Diaceturia. The complications and sequelæ are fully considered, as is the diagnosis, prognosis and treatment. Duodenal Ulcer forms the subject of a short appendix to the above article. An able monograph on Tumours of the Stomach is from the pen of Dr. Hale White. Short accounts of Subphrenic Abscess and Diaphragmatic Hernia are given by Dr. Lee

Dickinson. A succinct essay on Abdominal Diagnosis from a Gynæcological point of view is contributed by Dr. Playfair. Enteroptosis is treated by Mr. Treves. The normal mechanism of the suspension of the various abdominal viscera is first considered, and then the displacements undergone by the viscera severally are discussed. The commonest of all these conditions, viz. movable kidney, is reserved for a future article. The author then passes on to general ptosis of the abdominal viscera or Glenard's disease. Its results and treatment are described and illustrated by three well-marked cases.

The next section of the book is devoted to diseases of the Peritoneum; it begins by an article on Acute Peritonitis, which is written by Mr. Treves. After a few pregnant general considerations the author proceeds to enumerate the chief varieties of peritonitis classified according to their cause. A table of 100 cases of peritonitis from the records of the London Hospital is given. The symptoms are next discussed, and numerous temperature charts appended. The course, termination, and prognosis of the disease are then considered, and the article closes with a clear enunciation of the lines of treatment, operative or medicinal, to be adopted. The remaining part of this section is written by Dr. Allchin. The author first directs his attention to Acute Peritonitis of Undetermined Nature. Simple Chronic Peritonitis is then dealt with, subsequently Tubercular Peritonitis, and finally New Growths of the Peritoneum. From the brief sketch given above it will be obvious that the whole subject is very thoroughly treated, and that all of interest to the physician finds very ample consideration.

The concluding division of the volumes is devoted to Diseases of the Bowels. The subject is opened by an essay from the pen of Dr. Lauder Brunton on the Physiology of Fæcal Evacuation and Constipation. The author considers fully the connections between the central nervous system and the intestines, and discusses the influence of emotions upon intestinal peristalsis. Under the head of Constipation Dr. Brunton discusses its causes and treatment, position playing an important part, relief from habitual constipation being occasionally obtained by advising the patient to defæcate in the crouching position. The essay on Diarrhœa is from the pen of the same author, and forms an admirable study of the subject. Dr. Rolleston contributes an article on Diseases of the Small Intestine, and Dr. Hale White a short monograph on Colic. The editor has done well to entrust a special article on the Diarrhœas of Children to Dr. Eustace Smith; this, for the general practitioner, most important subject, is exhaustively treated by the author, who, from the fulness of his clinical experience, handles the subject of treatment especially well. Sprue or Psilosis is well treated by Dr. Patrick Manson.

Mr. Frederick Treves writes an account of Intestinal Obstruction; physicians will find this essay most useful for reference. It is very full, and well classified, so that the reader can easily find what he wants. The essay on Perityphlitis, or Peritonitis localised in the region of the Cæcum, is from the pen of the same author, and forms a complete clinical study of the subject. A carefully written monograph, by Dr. Hale White, upon Diseases of the Colon, and a short note on the Differential Diagnosis of Diseases of the Rectum and Anus, by Mr. Allingham, conclude the volume.

Vol. iv. opens with a section on Diseases of the Liver. This subject is introduced by four monographs of general interest on the Anatomy and Physiology of the Liver, Congestion of the Liver and Jaundice by Dr. William Hunter. The same author subsequently contributes special articles on Toxæmic Jaundice, Weil's Disease, and Acute Yellow Atrophy. Dr. Hale White writes a succinct account of Perihepatitis and Hepatic New Growths. The difficult medico-surgical subjects of Diseases of the Gall Bladder and Bile-Ducts and Cholangitis are ably handled by Mr. Mayo Robson. The great progress which has of late been made in the treatment of these affections will render Mr. Robson's article, which is quite up to date, of especial value to physicians. We find it odd, however, that no mention should be made in the bibliography of a book recently written upon this subject by Mr. Waring. The section concludes with an essay on Diseases of the Pancreas by Dr. Fitz.

The second division of the volume is devoted to Diseases of the Kidneys. Dr. Rose Bradford writes a complete essay on the General Pathology of the Renal Functions. The first part of the essay is devoted to abnormalities in the urine and their detection. The second part concerns itself more especially with the General Pathology of Renal Disease, in which are comprised a short discussion of Dropsy and Uræmia. Prof. Alexander Macalister contributes an article on Nephroptosis, or Moveable Kidney, to which is appended a rich bibliography. Dr. Howship Dickinson writes a complete essay upon Diseases of the Kidney characterised by Albuminuria. The Diseases of the Kidney which admit of surgical treatment form the subject of a comprehensive article by Mr. Henry Morris.

The third division of the volume occupies itself with the Diseases of Lymphatic and Ductless Glands, in which are included Diseases of the Thyroid Gland, the Spleen, Supra-renal Bodies, Hodgkin's Disease, and Scrofula. This section concludes with a monograph on Obesity by Sir Dyce Duckworth. The article contains a discussion of the various methods of treatment adopted in obesity, such, for instance, as Banting's, Salisbury's, Oertel's, &c., and a useful dietary adopted by the author in his own practice.

The fourth part of the book is devoted to Diseases of the Respiratory Organs, and comprises articles by Dr. Ransome on the General Pathology of Respiratory Diseases, and the Treatment of Asphyxia, and one on Physical Signs of Diseases of the Lungs and Heart by Dr. Hector Mackenzie. The volume concludes with a section on Diseases of the Nose, Pharynx, and Larynx. The articles in this last section are from the pen of nose and throat specialists, and include contributions by Sir Felix Semon, Dr. Watson Williams, Dr. Greville Macdonald, and Dr. de Haviland Hall.

The editor and his collaborators are again to be congratulated upon these further fruits of their labours. To compare one volume of the system with another would be idle. The impression of the reviewer is, however, that the present volumes, if rather less academic than their predecessors, fulfil to a remarkable degree the wants of the student and practitioner of medicine.

F. W. T.

ELECTRO-CHEMISTRY.

The Elements of Electro-Chemistry, treated Experimentally. By Dr. Robert Lüpke. Translated from the second, revised and enlarged edition by M. M. Pattison Muir, M.A. Pp. xv + 223. (London: H. Grevel and Co., 1897.)

THE parts of electro-chemistry dealt with in this book are the electrolysis of liquids, the theory of solutions and of osmotic pressure, and the theory of the galvanic battery. We gather from the preface that the main object of the book is to give a description of a number of experiments which illustrate the most important laws of the subject. We think that the author has been successful in this respect, and that the book will prove useful to teachers of physical chemistry. For the experiments described in this book are essentially lecture experiments; they are arranged not so much with the object of getting the greatest possible accuracy, but by means of simple apparatus to give striking illustrations of the points under discussion in the time available in a lecture. The experiments are described in sufficient detail to enable any one to repeat them without difficulty, and seem well adapted for the purpose for which they are intended. When, however, we leave the description of the experiments and come to the conclusions which the author draws from them, the book seems to us to be much less satisfactory; the statements are sometimes obscure, and occasionally erroneous. In the chapter on Faraday's laws of electrolysis the text seems to imply that the amount of salt electrolysed by a given quantity of electricity depends upon the time the electricity takes to pass through the electrolyte. The statements are on pp. 34 and 35, and occur in the definition of what the author means by the expression "electrochemical equivalent." This is quite different from the ordinary meaning of the term electrochemical equivalent of a substance. In this book the electrochemical equivalent is not, as hitherto, the number of grammes of the substance separated by the passage through the electrolyte of one unity of electricity, but the number of units of electricity required to separate the formula weight in grammes of the substance. We think that nothing but confusion can come from using the old expression in this new sense. This, however, is not the worst; for in defining this quantity the author says "the electrochemical equivalent—that is to say, the number of coulombs which causes the separation in *one second* [the italics are ours] of that fraction of the atomic weight of the metal or of the formula weight of an anion group which corresponds with a single valency." Of course the allusion to one second is quite misleading; the statement would have been equally true if one century had been substituted for one second. The point is unfortunately emphasised by the translator, who has a footnote to the effect, "the statement in the text may be put thus: the electrochemical equivalent is the number of coulombs that causes the separation of a gramme equivalent of a metal or anion group in one second." To make matters worse the following numerical example is given:

"Supposing that 20 c.c. hydrogen and 10 c.c. oxygen were obtained in an apparatus for electrolysis of water in three minutes, this is equal to the production of ·1667 c.c. explosive gas per second, and therefore the quantity of electricity was ·1667/·174; that is ·958 coulomb."

We have devoted some space to this point because it is one about which students are apt to fall into error, even when it is not suggested to them by the text-books. It is only fair, however, to say that the other chapters are much better than the one on Faraday's law. The chapter on the resistance of electrolytes is clear: it would have been more complete if it had contained an account of Mr. Whetham's experiments on the velocity of the ions. By a misprint the student, when determining the resistance of an electrolyte, is directed to adjust the resistances until the telephone sounds. In the chapters on osmotic pressure we have a clear account of the methods of preparing the semi-permeable membranes of ferrocyanide of copper. In connection with this subject we may remark that it would be interesting to have brought together all the various experiments made on the freezing and boiling points of organic solutions, so as to see how great, if any, are the divergencies from the strict accuracy of the law that substances in solution exert, as osmotic pressure, the same pressure as that which they would exert if they were to occupy as gases the same volume at the same temperature.

A large portion of the latter part of the book is taken up with the discussion of the theory of the galvanic cell; this is generally clear, and the experiments as usual are good and well described. It would be well, however, to discriminate in the theory of the potential difference between a metal and a solution of the salt of the metal between what is derivable from the theory of osmotic pressure and what is the result of further assumption. The theory shows that π this potential difference is expressed by an equation of the form

$$\pi = -a\theta \log \omega + \mathrm{C}$$

where θ is the absolute temperature, a a constant, ω a quantity proportional to the osmotic pressure of the action in the solution, and C a quantity of which all that is known about it is that it is independent of the strength of the solution, to write the expression in the form

$$\pi = a\theta \log \frac{\mathrm{P}}{\omega}$$

as is done in the text, is to assume that this constant is proportional to the absolute temperature, an assumption which ought to be justified by a series of experiments at different temperatures. We have no hesitation in recommending the book to teachers of physics, though we think it a somewhat dangerous book to put in the hands of a student at the commencement of his studies in electrochemistry.

OUR BOOK SHELF.

The Foundations of Scientific Agriculture. By Samuel Cooke, M.A., F.I.C., F.G.S. Pp. ix + 268. (London: Longmans, 1897.)

THE author is a Professor in the College of Sciences at Poona; his book contains the matter of a short course of lectures which he has been in the habit of delivering to a mixed class of students. In the course of 260 pages he treats of meteorology, mineralogy, rocks, soil, plant morphology, Indian crops, manures, implements used in cultivation, and mensuration. There is besides a scheme of qualitative analysis, a glossary of terms, and 129 examination questions. The book is written with ability and vigour, and evidently with a keen appreciation of the special needs of India. A full discussion of any subject in the brief limits to which the author confines himself is, of course, quite impossible, but enough is done to arouse interest and inquiry, and this apparently is the author's object. One paragraph we must quote. Alluding to the present effect of Government education in India, namely the withdrawal of the educated classes from agricultural pursuits, he says: "The first great step in renovating the profession of agriculture must come from the introduction of rational systems of national education. Governments must needs rectify their educational codes so as to give greater encouragement to studies tending to the enlightenment of rural populations in regard to food production and the relation of the science of rural economy thereto, combined with systematic demonstrations of economical methods of applying science to agricultural practice." This advice is equally needed in our own country. R. W.

The Zoological Record. Volume the Thirty-third; being Records of Zoological Literature relating chiefly to the Year 1896. By J. A. Thomson, R. Lydekker, R. Bowdler Sharpe, G. A. Boulenger, W. A. Herdman, B. B. Woodward, A. W. Brown, D. Sharp, Florence Buchanan, R. T. Günther, and R. von Lendenfeld. Edited (for the Zoological Society of London) by David Sharp, M.A., F.R.S., F.Z.S., &c. Pp. 890. (London: Gurney and Jackson, 1897).

GREAT credit is certainly due to the zoologists for the way in which they keep up their "Record," and for the punctual manner in which the annual volume is brought out. The zoological literature of 1896, which has appeared in various works, memoirs and periodicals all over the world during that year, has been already investigated and abstracted by these diligent recorders, and the summary of it appears in the present volume, the preface of which is dated in September last, and which was actually issued to the public in November. In no other branch of science, so far as we know, has a "Record" been kept up for so long a period, or issued so nearly up to date.

Besides eighteen records relating to as many branches of zoology, the present volume contains a very useful alphabetical list of the journals and other periodicals that contain zoological papers. This is arranged according to the abbreviated titles by which the journals are quoted in the various "Records," but the full titles are also added, so that we have here a complete and most useful catalogue of zoological periodicals. We have not counted their number, but the list takes up about forty-two closely printed pages, so that if we reckon them at a thousand we shall not be much over the mark. Besides analysing the separate publications referring to his particular subject, the unfortunate recorder may, therefore, have nearly a thousand periodicals to consult, in order to collect together the fragments relating to his particular subject. So great being the field of work in zoology alone, it is difficult to over-estimate the extent of the task about to be undertaken by the Royal Society of preparing an annual record of the literature of all branches of science.

As regards the individual records in the present volume, we observe with regret that several of them are without any sort of introduction. It is obvious, as we pointed out last year, that an introduction, specifying the principal points in which an advance has been made in the particular subject, is a necessary part of a good record. Such an introduction would be read with interest by many zoologists, who do not require to go into details very deeply—and should on no account be omitted. Considerable care and time is, no doubt, involved in its preparation; but we trust that Dr. Sharp, who in this respect himself sets an excellent example as regards the Insecta, will not allow any of his "recorders" to shirk this part of their task, however unwilling he may be to add to their arduous duties.

Annuaire pour l'An 1898, *publié par le Bureau des Longitudes.* Pp. 613 + 147. (Paris: Gauthier-Villars et Fils.)

Annuaire de l'Observatoire municipal de Montsouris pour l'Année 1898. Pp. 636. (Paris: Gauthier-Villars et Fils.)

THESE two year-books of scientific information annually increase in value by the addition of new data and revision of the old. The *Annuaire* of the Bureau of Longitudes has undergone several changes. In the astronomical part the tables of mean positions of stars supposed to be variable have been omitted, the tables of the elements of minor planets have been curtailed, and in the same way the number of coordinates referring to the orbits of double stars has been diminished. The table of elements of periodic comets only observed at a single apparition has been transferred to the *Connaissance de Temps*, but comets observed at a return are retained in the volume. The chapter on tides has been rearranged and revised, and new tables inserted. M. Moureaux contributes three new charts showing the magnetic elements in France, based on direct observations; the charts are for the epoch January 1, 1896. M. Berthelot brings up to date the tables in the section on thermo-chemistry. The articles in the *Annuaire* are all interesting. MM. Lœwy and Puiseux contribute a paper on recent progress in the knowledge of the lunar surface, obtained by means of photography; M. Poincaré contributes a valuable paper on the stability of the solar system; an account of Fizeau's scientific work is given by M. Cornu; and M. Janssen describes the work done at the observatory on the summit of Mont Blanc in 1897. Finally, there is an address by MM. Janssen and Lœwy, delivered on the occasion of M. Faye's jubilee last January.

The *Annuaire* of the Municipal Observatory does not cover so wide a field as that of the Bureau des Longitudes. It contains the results of observations made, during 1896, in the departments of meteorology, chemistry, micrography, and hygiene under the control of the Municipal Council of the City of Paris. In each of these branches, and especially in the sections of chemistry and micrography, a large amount of work was done beyond the mere compilation of statistics, and the volume is thereby rendered serviceable to all who are interested in the science of public health.

Mémoires de la Société de Physique et d'Histoire naturelle de Genève. Tome xxxii. Seconde Partie. Pp. lxxxi + 401. (Genève: Georg et C^{ie}. Paris: G. Fischbacher, 1896–97.)

THERE are five papers in this volume, illustrated by fourteen plates and numerous figures in the text. In a long memoir, Mlle. C. Schépiloff describes her researches on the nerves of the labyrinth or internal ear, and the functions of the brain and medulla of frogs, with a general comparison of the central nervous systems of various batrachians. A demonstration of a fundamental theorem referring to the primitive factors of prime numbers is developed by M. Ch. Cellérier. Anatomical researches on a number of plants are described by M. J. Briquet. M. P. de Loriol describes some echinoderms, and M. J. Briquet makes a contribution to a flora of Paraguay.

Elementary Practical Physiography. (Section I.) By John Thornton, M.A. Pp. vii + 311. (London: Longmans, Green, and Co., 1897.)

THE elementary stage of the physiography examination of the Department of Science and Art is now divided into two parts, the first part (Section One, as it is termed) dealing with the fundamental principles of physical science, and the second with physical geography as it is generally understood. The complete syllabus thus provides the outlines of an elementary course of general science. Mr. Thornton's book has been written upon the lines of the first part of the syllabus, and therefore it is limited to brief treatment of the elementary facts and principles of physics and chemistry. A large number of experiments are included, some of them good. The illustrations are also numerous, and some of them are original.

The Wealth and Progress of New South Wales, 1895-96. By T. A. Coghlan. Vol. i. Ninth issue. Pp. 491. (Sydney: Government Printer, 1897.)

THE difficulty in preparing a volume of this kind is to limit the information concerning the details of local affairs, and yet make them useful both locally and to the outside world interested in the features and progress of our colonial possessions. Mr. Coghlan, the Government Statistician of New South Wales, seems to have successfully adjusted the balance of the two interests, with the result that his volume appeals to all who wish to have accurate information concerning the active life of the Colony. Moreover, there are chapters on the history of the Colony, the climate, geological structure, physical configuration, fauna, flora, forestry and fisheries, and mines and minerals. The volume will be very serviceable for reference.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Glacial Period and the Irish Fauna.

IT has been shown by the work of many observers, in Scotland, Ireland, north-western England and the Isle of Man that during the Glacial Period the basin of the Irish Sea must have been filled with an ice-sheet. It is not probable, therefore, that the interesting speculations of Dr. Scharf on the origin of the Irish fauna (NATURE, October 28, 1897), in so far as they are based upon assumptions as to the glacial conditions of the Irish Sea, will meet with much acceptance among geologists.

There is one possible mode of migration for land-animals in formerly glaciated regions which I think has been too frequently ignored by students of the subject. I refer to the probability that the ice-sheet itself may have furnished a practicable route across narrow seas. In Prof. I. C. Russell's luminous description of the Malaspina Glacier of Alaska, we read that "a broad game-trail which had evidently long been used by bears, wolves, foxes and mountain-goats," skirting the Chaix Hills, "continued across the glacier 6 or 8 miles north-eastward to the Samovar Hills." Again, Dr. Scharf himself incidentally mentions that in Northern Europe "it is a well-known fact that reindeer are in the habit of travelling considerable distances on ice."

During my recent survey of the Isle of Man I have found abundant evidence to show that during the maximum glaciation an extraneous ice-sheet swept across the highest summit (2034 feet), and also that during the closing stages of the Glacial Period this ice-sheet melted away more rapidly in the vicinity of the island than in the surrounding obliterated sea-basin. Under such conditions the island formed a nunatak accessible for any animal which could cross the ice. And I think that the general circumstances attending the close of the Glacial Period indicate that most of the land surrounding the enclosed sea-basins in our latitudes might be in a condition to support animal life before the decaying ice-lobes had disappeared from these hollows. During the earlier stages of the Glacial Period, it is clear that the climate was such as to favour the accumulation of glaciers even at sea-level, and this condition persisted until ice-sheets of great thickness had covered the lowlands. This growth at length ceased; perhaps, as I have elsewhere suggested, in the east sooner than in the west, because of the greater amount of snowfall along the western periphery of the sheet.

In the northern part of the Irish Sea basin there existed a high plateau of ice, its surface probably not far, if at all, short of 3000 feet above present sea-level. An amelioration of climate set in, and progressed until, say, no permanent snow was possible at any altitude under 1000 feet. But the ice-sheet was already in possession, and by reason of its elevation would remain, throughout the greater part of its area, uninfluenced by this extent of change, or it might even still continue to grow where there was sufficient precipitation. In an ice-choked basin hemmed in by hills as is the Irish Sea, the discharge by flow alone was scarcely likely to keep pace with the surface accumulation.

Not until the climate became such that melting was in progress over the whole plateau would there be much general lowering of its surface. Under such conditions, as the elevation of the ice-sheet was equal to, or greater than, the uplands upon which it abutted, the snowfall could no longer remain permanently, even on the hilly ground. Hence, as the land emerged from its icy covering, it would remain bare, and ready to support vegetation. As on the Malaspina Glacier, even the ice itself, where covered with morainic débris, might become verdure-clad.

The melting influence of rain falling upon the ice-sheet would be distributed equally over the recipient surface, for its superfluous heat would be at once absorbed. But whatever rain fell upon the emerging land could gather and flow in comparatively warm streams, capable of exerting a considerable differential effect where they impinged upon the margin of the ice. There would thus be a general tendency for the melting mass to shrink down more quickly in the vicinity of land; and this effect would be accelerated as the lower levels were uncovered.

These are the conditions disclosed by the field evidence in the Isle of Man, and that life existed under such conditions is proved by the presence, in one of the gravel-terraces of this period, of the arctic fresh-water crustacean *Lepidurus* (*Apus*) *glacialis*, which lives now in icy pools near glaciers in Norway and Spitsbergen, along with an arctic willow, *Salix herbacea*, and a few other plants of wider range.

The Irish Elk reached the Isle of Man about this time, and I think it probable that it crossed from the mainland on the waning ice-sheet. The evidence is altogether unsatisfactory for a Post-Glacial land-connection, as Mr. P. F. Kendall has shown.

The distance between the nearest points of Ireland and Scotland is about the same as between the nearest points of the Isle of Man and Scotland, and I see no reason why certain elements of the Post-Glacial fauna of Ireland should not have been similarly introduced by the ice-bridge. At any rate, in view of the above-quoted data furnished by the Alaskan Glaciers, this appears to me to be a legitimate supposition, and one which is in keeping with the general trend of the geological evidence.

G. W. LAMPLUGH.

The Variability of Mira Ceti.

THE notes in NATURE, December 2 and 9, are very welcome, as they show more interest in o Ceti than in late years, and especially as from present information there have been but few observations from this side on the recent appearance. It seems that I have seen, so far, more of the star than any one else.

The maximum of Mira, following previous ephemerides, was due October 1. But *The Companion* and Chandler have added a correction of about forty days, and given the date as November 9. This phase appears to have occurred this season November 30, which is sixty days late. But it is not at all improbable that another maximum may be observed, although the star seems now to have broken away definitely. It was a step or so brighter than a star (3·99 H.P.) last night, and is unchanged to-night except in colour. Its reddish cast to-night, judging from some past experiences, indicates a change in light, and another rise may occur.

The magnitude November 30 was 3·2, Gamma Ceti being 3·59 Harvard measurement.

It is remarkable that while there is agreement as to the light-curve of Mira for three years, the dates of maximum are as much as five weeks apart. But there still remains some doubt as to the fluctuations in 1894-95; and did not Mr. H. M. Parkhurst confirm the present writer's observations of that apparition, they would have been thrown out of court. And some doubt would attach to Mr. Parkhurst's did not an observer at Moscow, mentioned in NATURE, confirm both of us.

DAVID FLANERY.

Memphis, Tenn., U.S.A., December 24, 1897.

RECENT SEISMOLOGY.

I.—EARTH MOVEMENTS WHICH WE FEEL.

THE circumstances which led to the recent advances in seismological science are closely connected with an earthquake-like reformation in the policy of a foreign country. The country referred to is Japan, and the story of the changes it so suddenly effected is well known.

To bring about the new conditions engineers, architects, doctors, lawyers, surveyors, literati generally, together with representatives of a variety of trades, were invited to the birth of a new *régime*.

The engineers built their bridges, but found that they were shaken down; architects were disheartened that their houses were unroofed and subjected to processes of shattering; doctors learned that seismic disturbances might be followed by nervous prostration, tetanus and erysipelas; lawyers were perhaps perplexed when their opinion was required respecting the ownership of superimposed properties; the surveyors saw that the area of a piece of ground was not necessarily a constant quantity, and that gate-posts, on which bench-marks had been placed, might change their position by hopping—in short, one and all were impressed by the mobility of their near surroundings, and were often alarmed by rude awakenings.

The result of this was that an unusually keen interest was taken in all that pertained to earthquakes, and the new-comers, one and all—by speech, writing, or by special investigation—contributed to the advancement of seismological knowledge.

Amongst the many workers stationed in Tokio we find the names of Verbeek, Wagener, Knipping, Chaplin, Mendenhall, Ewing, Gray, Perry, Ayrton, West, Alexander and Knott; whilst amongst the Japanese, no less enthusiastic than their new colleagues, we see the names of Sekiya, Omori, Hattori, and many others. Outside assistance came from Bissett and Talbot in Yokohama, Fukushi in Sapporo, and a number of other workers throughout Japan.

At this time Tokio was in reality a city of many inventions, all of which were for the purpose of obtaining trustworthy information about earthquakes; their name was legion, and it is no exaggeration to say that of seismographs, seismoscopes and seismometers, more than one worked with at least fifty different devices.

One great problem which presented itself was to suspend a mass of material so that at the time of an earthquake it should practically remain at rest. The solution was first sought for in the bob of an ordinary pendulum. It being supposed that greater stability would be attained if the lengths of the pendulums were increased, three enthusiasts, in order to obtain a support from the roof timbers of their houses, cut holes through two ceilings, and the bobs of long pendulums were even to be seen in drawing-rooms.

Inasmuch as it was found that whenever a heavy earthquake occurred these pendulums were caused to swing in some instances so violently that apparatus in their vicinity was wrecked, attempts were made to render them dead-beat and next astatic, and a series of experiments were started which it would require pages to describe.

Following ordinary pendulums came horizontal pendulums, combinations of ordinary and inverted pendulums, rolling sphere and cylinder seismographs, ball and plate seismographs, parallel motion seismographs, and such a multitude of devices—not only for recording earthquakes, but also for timing them—that about 1883 it was decided to hold a public exhibition of earthquake apparatus. This was held in Uyeno Park; it lasted three days, and people flocked in such numbers to see the exhibits, that police assistance was called in, and the sight-seers were admitted in batches of about fifty.

Although in Japan, as a whole, there are on the average two or three earthquakes per day, whilst at many stations fifty to eighty shocks may be recorded during a year, because the disturbances came at unexpected times and from unexpected quarters, the appetite of the Tokio seismologists was so far from being satisfied that a series of experiments, which extended over several years, were inaugurated on artificially produced earthquakes.

The shakings were obtained at first by the fall, from heights up to about thirty feet, of a ball approaching a ton in weight, and subsequently by the explosion of charges of dynamite and gunpowder in boreholes.

The resulting vibrations—longitudinal, transverse, and vertical—were recorded at a series of stations so arranged in electrical connection that the time of any vibration could be noted to within a small fraction of a second.

Spare time was occupied in analysing earthquake registers and the carrying out of seismic surveys. The first of these was on an area of about nine acres, the next extended over the city of Tokio, whilst the last embraced a district some 500 miles in length, extending from the capital to the northern island.

In the first of these surveys a number of similar seismographs, one of which was in a pit, were connected together in the same manner that instruments had been connected when studying the effects of artificially produced disturbances; but with the latter, although a certain number of seismometers and seismographs were employed, the records were largely dependent upon information received on post-cards respecting the time at which a disturbance had occurred, and observations respecting its duration, direction, and severity.

This work, together with investigation on the volcanic phenomena of Japan, the more or less mysterious sea waves which occasionally inundated the coast, the supposed relationship that might exist between magnetic, electric, and seismic phenomena, the effect of earthquakes upon the lower animals, for studying which Prof. Sekiya kept a pen of pheasants, and a variety of other investigations formed interesting occupations for many.

On February 22, 1880, seismic enthusiasm was brought to a head by a very severe shaking, which gave to Yokohama the appearance of a town which had been bombarded. Taking advantage of the disturbed state of mind common not only to those who were repairing their roofs and chimneys, but to the whole community, a meeting was called, and in less than sixty minutes the Seismological Society of Japan, with its rules and regulations, was established. Many paid their subscriptions before they left the hall.

One great incentive to the work was competition between rival bodies, and many a time a member of the new Society, because his seismogram of the last quake was insignificant as compared with that obtained by a neighbour, after bitter controversy returned homewards from a meeting with a sad heart. At first these differences were regarded as the results of differences in the adjustment or construction of the instruments which had been employed, and it was not before sharp battles had been fought that it was recognised that the differences were due to differences in the localities of installation.

The feeling which at this time prevailed was not unlike that which characterises many sportsmen who, in the ordinary affairs of life, are everything that is admirable, but in the excitement of the field the desire to excel exceeds all others.

After seventeen years the seismic fever has abated, and we say with the poet—

> "*Haec olim meminisse juvabit.*"

Now what was the good of all this expenditure of time and money in the endeavour to trap the fleeting earthquake? The earthquake-hunters of Japan, no doubt, saw a little that was before them; but now, when they stand beside the elaborate seismographs of the present day, costing 50*l.* or 100*l.*, and look backward upon the days when pins were propped up in rows to act as seismoscopes, and twopence would buy a bit of string and a bob for a pendulum, I do not think that it was ever anticipated that the study of earthquakes would lead to the knowledge which we now possess.

In seismometry we have seen the gradual evolution of several types of instruments which give faithful records of the amplitude, period, duration, and the time of occurrence of all ordinary earthquakes.

For this work we are greatly indebted to Ewing and Gray, and it is fair to say that the seismometry of Japan has done much to revolutionise seismometry throughout the world. The examination of earthquake records completely changed our ideas of earthquake motion, and we learned that nearly all the formulæ which up to this time had been employed to calculate earthquake elements had been founded upon a wrong hypothesis. The fact that the period of earthquake motion increased as it died out and as it radiated, coupled with a discussion of the observations made upon the movements which had occasionally been observed in the bubbles of levels, magnetographs, and other instruments, and, above all, that now and then unfelt earthquakes had been recorded, enabled one investigator to state, fifteen years ago, that it was "not unlikely that every large earthquake might with proper instrumental appliances be recorded at any point on the land surfaces of our globe"—a prediction which of late years has been amply verified.

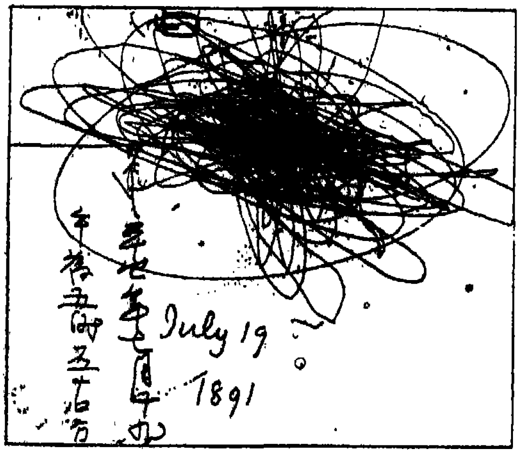

FIG. 1.—Static diagram of the earthquake of July 19, 1891, showing the complicated direction of motion common to most earthquakes. (Milne.)

It was found that modified forms of seismographs might be used to record the joltings of a railway carriage, and thus to indicate defective points along a railway line. Another application of seismometry has been to measure the steadiness of a locomotive, which in part depends upon the manner in which it is balanced. On Japanese railways this has been turned to practical account, with the result that a saving of from 1 to 5 lbs. of coal per mile per locomotive has often been effected. The modern seismograph is also used to measure the elastic vibrations of bridge work, buildings, and steamships.

The greatest material benefits which recent seismological investigation has conferred upon the world are those which have resulted in minimising the destruction of life and property. The builder now, rather than making a structure strong because an earthquake is strong, has before him definite measures and a clear knowledge of the character of the forces he may expect to meet. Given the dimensions and tensile strength of a body that has been overturned or shattered, we can calculate the maximum acceleration to which the same has been subjected, and that quantity is practically identical with that derived from a seismogram.

FIG. 2.—Earthquake of June 20, 1894, recorded at the Science College of the University of Japan. The upper figure is the S.E.-N.W. component; the middle, the N.E.-S.W. component showing preliminary vibrations, the shock, and concluding vibrations; and the lower, the vertical motion. The intervals are the seconds of time. (Ewing's Seismograph.)

By experience we know the maximum acceleration which may be expected in a given district or on a given site, and we can therefore proportion a structure to meet the known conditions.

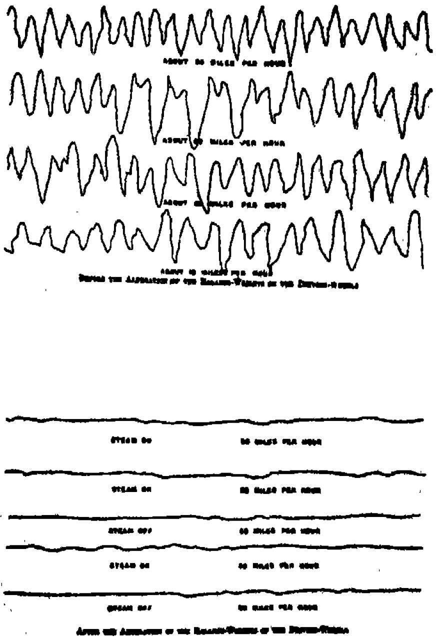

FIG. 3.—The fore and aft motion of a locomotive as balanced in England and after rebalancing in Japan, by which a safe speed has been increased from 28 to 35 miles per hour, and coal saved. (Macdonald.)

The fact that the new rules take into consideration that buildings have to withstand measurable stresses, due to more or less horizontal displacements applied at the foundation, have been largely adopted in the building of houses and the works of engineers, is a testimony that they have been well worthy of consideration. The correctness of the new methods is found in the fact that in very many instances tall chimneys, as well as those of ordinary buildings, together with buildings themselves embodying the new principles, remain standing, whilst the old types have fallen or at least been shattered. When we remember that on June 15, 1896, Japan lost nearly 30,000 of her people by earthquakes and sea-waves, that on October 28, 1891, the loss of life was about 10,000, and the cost to restore railways and other works involved an outlay of approximately 3,000,000*l.*, that the Calcutta earthquake on June 12, 1897, is to be followed by an expenditure of 35 lahks of rupees for the restoration of public works, for the payment of which the Chief Commissioner of Assam applies for a grant from the Imperial revenue, the importance of anything which will minimise the effects of these great catastrophes can not be over-estimated.

In Japan engineers and builders are already crystallising the results of experience and experiment, and stereotyped methods of construction are being gradually abandoned, with the result that after fire, flood, or earthquake, or as other opportunities present themselves, new types of structure are growing up, which have already shown themselves to be better than the old.

FIG. 4.—Gravestone as seismometers, indicating direction and intensity of movement. (Omori.)

Even if these results represented everything that the pioneers of the new seismology had achieved, they carry with them a feeling of satisfaction that the study of earthquakes has not been altogether unfruitful, but has led to that which is practical and simple in its application.

The experiments in which vibratory movements of the ground were produced by artificial means, whilst reproducing and affording an explanation of many phenomena observed or expected in earthquake disturbances, directed attention to others, the existence of which was for the first time rendered probable.

The velocity of propagation of wave motion evidently increased with the intensity of the initial disturbance; it was greater for vertical and normal than for transverse waves, whilst motion was propagated more rapidly to stations near an origin than between stations which were at some distance from the same.

The period of the movements increased as a disturbance died out, or as it radiated. A wave which had a slight notch upon its crest by the gradual growth of the riplet, as the motion radiated from its origin, was seen to change into a double wave. Within 50 or 100 feet of an origin, the first movement was due to a wave of compression, but beyond this distance a separation between normal and transverse movements was not observable.

The manner in which a shadow area, formed behind a cutting or hill, was invaded by movements creeping round the two ends of the obstruction was remarkable. These and many other results were confirmed and extended by actual seismograms obtained from a series of stations situated on a piece of ground less than ten acres in area. The motion on one side of this piece of ground was invariably so much greater than it was upon the other side, that it afforded an explanation of the peculiar distribution of ruin, sometimes observed in a city after a disastrous earthquake.

The fact that the side of greater motion was that, where the ground was soft, and the confirmation of this by observations in other localities, was a matter that attracted the serious attention of architects and builders. Another observation which has received many practical applications, especially in connection with the foundation of buildings, was that at a depth of 10 or 20 feet the movements of the ground were found to be less than they were upon the surface.

FIG. 5.—Destruction of an ordinary European structure (a cotton mill at Nagoya) by the earthquake of October 28, 1891. (Burton.)

The seismic survey of North Japan, which has been extended to cover the whole empire, shows clearly that the volcanoes, extending for the most part along the backbone of the country, have no immediate connection with the earthquakes, nearly all of which originate along the eastern seaboard. Many of the largest of these have their home beneath water which in certain places exceeds a depth of 4000 fathoms, and it is in these sub-oceanic recesses at the base of a continental dome where a certain class of geological activities, which from time to time are announced to us by the shaking of the ground, are most pronounced.

The earthquakes of one region have been separated from those of another, whilst the land area which was sensibly shaken by each disturbance is well known.

The advantage of these registers when, for example, we seek for a connection between earthquakes and lunar attraction, or the rising of the tide upon a coast, because these influences attain a maximum in different localities at different hours, must be apparent.

Thanks to Dr. C. G. Knott, who first subjected earthquake statistics to rigid analysis, to Dr. C. Davison, who so ably emphasised and extended these methods of investigation, and to Dr. F. Omori, our knowledge of annual, semi-annual, diurnal, and other earthquake periodicities has been placed on a more certain basis than it formerly occupied.

Without entering into the observations which have been made upon magnetic phenomena, sea waves, sound phenomena, the behaviour of lower animals, and a variety of other subjects connected in a greater or lesser degree with exhibitions of seismic force, what has been said indicates that the study of earth movements, which we feel, have not been without profit.

In Japan, at its University, there is a chair of Seismology; a bureau, which in 1895 controlled 968 observing stations; whilst the Government give liberal support to a committee of engineers and architects, whose duty it is to carry out investigations which may lead to the mitigation of earthquake effects.

Notwithstanding the opportunities which Japan offers to make such investigations, it is worthy of note that two trained men were ordered by the Government of that country to report upon the recent earthquake in Assam. This they have done, and no doubt Japan is now in a position to avoid forms of construction of which she was hitherto without experience.

J. MILNE.

(*To be continued*).

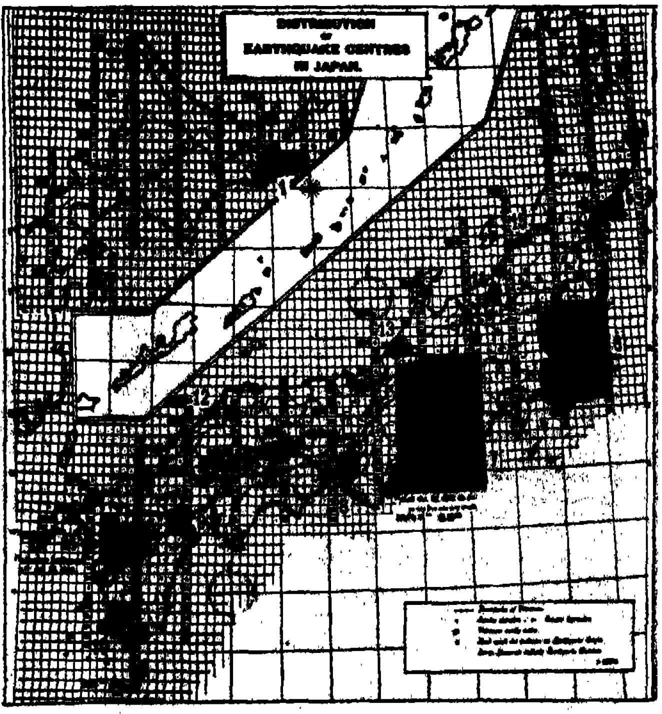

FIG. 6.—Map showing the *origins* of 8331 shocks recorded between 1885 and 1892 in Japan. The large dots indicate the positions of active volcanoes. The small dots indicate the origin of different earthquakes which group themselves into fifteen districts, each marked by a large numeral. (Milne.)

THE AREQUIPA OBSERVATORY.

PROF. PICKERING has conceived and carried to a successful issue many projects that require both mechanical skill and confidence in his resources. In the gradual development of these schemes, we have seen the modest row of volumes, that contained the annals of the Harvard Observatory prior to his directorate, increase to imposing proportions. We know how deftly he holds the strings that control the operations of many departments outside Harvard, and how efficiently he copes with the work that a whole army of astronomers submits to his examination. But assuredly the equipment and maintenance of the observatory at Arequipa will be remembered as one of his most successful achievements. We are apt to think of a subsidiary observatory, especially when situated in a position difficult of access, as one temporarily occupied for a definite purpose, and requiring but few instruments, mounted in buildings of slight construction. But the energy of Prof. Pickering has established in South America an observatory that a State government, having the resources of a public exchequer at its will, might look upon with satisfaction. We reproduce in Fig. 1 (p. 250) the general appearance of this astronomical station, some 8000 feet above the level of the sea, and a mere glance will show or suggest how varied must be the work of the observatory, in which all the telescopes under the different sheds are kept constantly employed through every clear night. In the illustration the observer's residence is on the extreme right. Starting from that point and taking the several buildings in order as we approach the left, we have first of all a laboratory with developing rooms attached, next a shed containing a 5-inch visual telescope, which leads on to another containing a 20-inch mirror of short focal length, figured by Dr. Common for the observation of the solar eclipse of 1889. We then pass a building containing the principal clocks and a transit instrument, and come to that containing the Bache telescope of eight inches aperture. Next to this is the 13-inch Boyden telescope under a cylindrical drum roof. To the left of this, and before we come to the buildings occupied by the assistants, is a telescope with a Voigtländer portrait lens as an objective in which are taken photographs of four hours' exposure of faint nebulous regions of considerable extent. To this list of instruments must now be added the Bruce photographic telescope, having an objective doublet of 24 inches aperture, and from Prof. Pickering's last report we learn that a transit photometer similar to that in use at Harvard has been erected. Photographs of all the bright stars from the North to the South Pole are now obtained when they cross the meridian on every clear evening, either at Cambridge or Arequipa or both.

We shall get a good idea of the use to which these instruments are put if we describe some of the illustrations that Prof. Pickering has given in the volume containing the "Miscellaneous Investigations of the Henry Draper Memorial." We have first of all a picture of the Southern Cross on which abuts a portion of Herschel's Coal-sack region, taken with the Bache telescope, exposure 127 minutes, covering an area ten degrees square. We might make this plate the excuse for discussing several points of great interest. First, should photographs represent the stars on paper as positives or negatives? Prof. Pickering, by his practice, is clearly in favour of exhibiting the stars as black dots on a white ground. In this decision he has been guided by the use of ordinary star charts, in which there has never been any question as to the most convenient method of representing stars, and to which astronomers have already accommodated themselves. With regard to the important question of the scale to be adopted, and which in this telescope gives three minutes to the millimetre, it will be admitted that it is too small for star charts, if faint stars are to be represented. Prof. Pickering says distinctly that the images are too near together to be conveniently studied. It is mainly for this reason that we do not reproduce the plate, which would have been interesting since it affords a good illustration of the difference between photographic and visual magnitudes. γ Crucis, which has a spectrum of the third type and is very red in colour, appears on the print much fainter than δ, while ε Crucis, also a third type spectrum star, which to the eye is so conspicuous that it is usually inserted in rough diagrams of the constellation, as for example on the Brazilian postage-stamps, is on the negative so faint, that it would not be selected as one of the principal stars.

The trifid nebula in Sagittarius, taken with the same telescope and exposure, illustrates still more completely the inadequacy of this scale for star maps, but brings out well the structure of such portions of the Milky Way as fall on the plate. This particular region is remarkable for the number of gaseous nebulæ that fall within the area covered by the plate. One-tenth of the whole number hitherto discovered in all parts of the sky are here depicted; but almost every night increases the number of these objects in our catalogues. The examination of only two plates taken with the Bruce telescope and objective prism showed that the spectra of six known nebulæ were gaseous. We pass over the photographs of the Magellanic clouds, reproduced in the volume by contact printing, and reach the nebulous region round η Argus, or as Prof. Pickering prefers to call it η Carinæ. This has been the subject of so many illustrations that its main features are well known. It serves here as an admirable object on which to test the advantages of increased scale. Three different enlargements of the original negative are given, one taken with the Boyden telescope. Prof. Pickering apparently prefers a scale of ten seconds to the millimetre at least for districts where the stars are much crowded. This size seems to him to possess the advantage of showing nearly all the stars that can be seen upon the original negative, without rendering the images inconveniently large. On a careful comparison being made between the nebulas recorded on the plate and those given in Dreyer's catalogue one very important difference was noted. N.G.C. 3199 was observed by Herschel on four nights, and on each occasion described by him as very large and bright. There seems to be no doubt about the place of the nebulæ so described, as a curved line of stars noticed by Herschel is recognisable. But of the nebula itself there is no trace. One seems to have another instance of variability similar to Hind's nebula in Taurus. The spectra of the stars contained in this portion of the sky is also illustrated. By placing a prism in front of the objective of the Bache telescope and exposing for 140 minutes, we have, exhibited on one plate, more than 1000 spectra. Where the stars are densest the separate spectra cannot be recognised in the print, but on the original negative even these can be conveniently classified. No less than fourteen stars within this limited area, out of a total of sixty-three already catalogued, show a spectrum which consists mainly of bright lines.

The cluster known as ω Centauri is admittedly the finest in the sky. We reproduce, in Fig. 2, a reduced form of the illustration of this superb object as it depicts itself in the Boyden telescope after two hours' exposure. In one particular this picture fails to do justice to the original in the sky. The photographic images have sensible diameters amounting to, perhaps, three seconds of arc. This suggests the possibility that some stars are hidden by those nearer to us, but, as Prof. Pickering remarks, in the telescope each separate star can be distinguished, and therefore it is not probable that any star is actually occulted. The only two other clusters in the sky, which though far behind, are to some extent comparable with ω Centauri in brilliancy, are 47 Tucanæ, and the well-known cluster in Hercules, Messier 13. In each of these clusters Prof. Bailey and the staff have made attempts to count the number of stars visible, and Prof. Pickering has submitted the results to a mathematical analysis. He finds that the number of stars per square minute of arc increases in arithmetical progression as the centre is approached, and that the theoretical number derived from his formula agrees fairly well with the actual count. In the case of ω Centauri the number actually counted was 6316, while

Fig. 1.—Arequipa Station from the south-west.

theory gives 6475. The stars in the cluster 47 Tucanæ are divided into bright and faint stars. The number of each counted is 1495 and 740 respectively, while theory gives 1495 and 734. We, in the Northern Hemisphere, think Messier 13 a magnificent object, but the number of stars counted is only 723, while theory assigns one more. It says much for the admirable character of the photographs that, notwithstanding the closeness of the stars and the consequent tendency for the individual members to be obscured by the spread of the images, it should be possible to count the stars with approximate accuracy. And further, the individual stars are so distinct that variations of brilliancy are easily recognised. In this way no less than eight new variable stars have been detected in the cluster of ω Centauri, while six have also been discovered in the south following portions of the cluster 47 Tucanæ. The occurrence of a large proportion of variable stars in star clusters is a most interesting subject of inquiry. Counts have been made of the number and distribution of stars in several clusters, with the result that 400 were found in these objects. Nearly 7000 estimates were made of the brightness of the 120 variables contained in ω Centauri, and of the eighty-five variables in Messier 5.

It might be thought from this short summary that Prof. Pickering is interesting himself mainly in these very interesting objects. It must be remembered, however, that they come naturally before him in the course of a complete survey of the whole heavens, and that while we have referred to only a few plates, the entire scheme had on January 1, 1895, resulted in the collection of no less than 12,777 plates taken by the Bache, and 6281 by the Boyden telescope. Such a mass of information is likely to yield many discoveries, some of which are given in this volume before us, but to which we cannot adequately refer. This is the case with the discussion of that interesting variable, Nova Normæ, which in nineteen days sprang from a magnitude below visibility to the seventh, and then gradually faded away, passing beyond the reach of the most powerful telescopes in about two years. Comparisons of its spectrum with that of Nova Auriga are given, showing the hydrogen lines bright in both stars, and each accompanied by dark lines of slightly shorter wave-length.

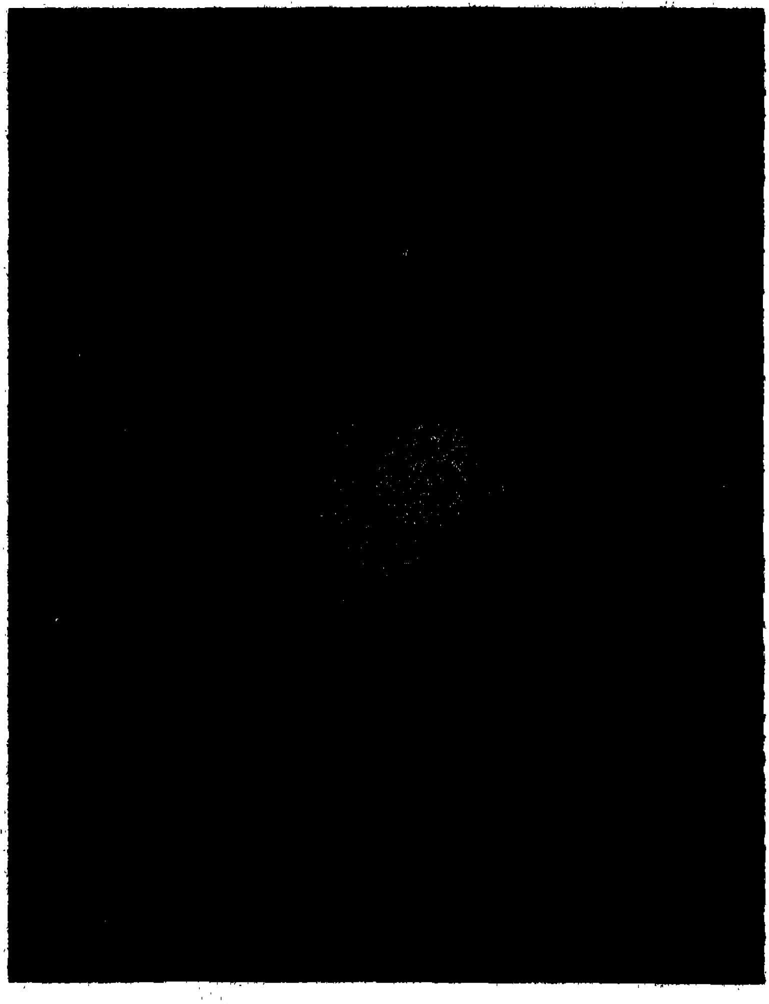

Fig. 2.—ω Centauri.

ERNEST HART.

MR. ERNEST HART, editor of the *British Medical Journal*, died on January 7 at Brighton, where he was staying for the benefit of his health. He had suffered from diabetes for many years, and had been compelled to submit to amputation of the leg last September. The operation though successful only postponed the fatal termination of his illness.

Ernest Hart was born in London in 1836, and received his early education at the City of London School during the headmastership of Dr. Mortimer. At school he performed prodigies of prize-winning, and would have taken up a scholarship to Cambridge, in the same year as the late Sir John Seeley, but for the disabilities under which the Jews then lay at the older Universities. He resolved to enter the medical profession, and joined Lane's School, then attached to St. George's Hospital. He became a member of the Royal College of Surgeons in 1856, and after serving the office of Resident Medical Officer of St. Mary's Hospital, was appointed Ophthalmic Surgeon and Lecturer on Ophthalmology at that hospital. Subsequently he became Aural Surgeon also, and for some years held the office of Dean of the Medical School. He was already a valued member of the staff of the *Lancet*, then still directed by its founder, Mr. Thomas Wakley, M.P.; and though he engaged, not without considerable success, in the practice of surgery, and especially of ophthalmic surgery, his heart was in public work. Even as a student he had given evidence of his natural bent by organising a society, to which he acted as secretary, which had for its object to ameliorate the depressing and injurious conditions under which the Naval Medical Service then laboured. This movement was completely successful, as was also another in which he took an active part as one of a commission appointed by the *Lancet* to inquire into the nursing and other arrangements of the poor law infirmaries in London. The

Home Secretary was by the facts thus brought to light led to appoint a special committee, and, as a result of its report, Gathorne Hardy's Act was passed. This Act, by the establishment of the Metropolitan Asylums Board, and in other ways, has worked an immense improvement in the care of the sick, infirm, and imbecile poor.

Ernest Hart's great opportunity came in 1866, when he was appointed editor of the *British Medical Journal*, then, as now, published by the British Medical Association. He threw his whole energies into the task of making the *Journal* more useful to practising members of the profession, while at the same time extending and consolidating its influence on the course of public health legislation and administration. A special Parliamentary Bills Committee was appointed. Of this he was elected chairman, and through it he did most of the work which earned him his reputation as a sanitary reformer. Among the subjects to which he gave special attention were the amendment of the Public Health Acts, the introduction of the system of notification of infectious diseases, and of the registration of plumbers; the improvement of factory legislation, and of local administration in public health matters, the abatement of the smoke-nuisance, and the desirability of replacing arm-to-arm vaccination by the use of calf lymph. On all these matters his industry in accumulating facts and his power of arranging them into a logical statement of the need for reform and the mode in which it should be carried out, were of great value in moulding professional and public opinion.

His chief claim to recognition as a man of science rests on his life-long study of the dissemination of certain infectious diseases by water specifically contaminated. His attention was early directed to the matter during the investigations of the curious outbreak of cholera at Theydon Bois in 1865, and of the more extensive epidemic in the East-end in 1866. Subsequently he gave much attention to the question of the dissemination of typhoid fever by the same vehicle, and gradually accumulated a mass of evidence drawn from the successive object-lessons provided by municipal authorities in various parts of the country, which put beyond question the fact that, whatever may be the cause of the endemicity of typhoid fever, the specific contamination of drinking water is the immediate cause of epidemics of that disease. In 1894, during a tour in India, he expounded this doctrine and its application to the conditions of Eastern life. The greater degree of importance which the Government of India is now disposed to attach to bacteriological investigations is to be attributed in no small degree to Mr. Ernest Hart's forcible advocacy.

His chief recreation in his later years was the study of Japanese art. He formed a large and choice collection. A few years ago he visited Japan, in the company of his wife, who was also his companion during his journeyings in India and Burmah, and lives to mourn his loss.

He was a man of great alertness of mind, of untiring industry, of steady perseverance, and strong convictions. These sometimes brought him into controversies in which he showed himself a hard hitter; but he was always ready to sink personal differences for the public good.

NOTES.

A CABLEGRAM received from Ratnagiri on Saturday last, informs us that H.M.S. *Melpomene*, having on board Sir Norman Lockyer, K.C.B., F.R.S., and other members of his eclipse party, has arrived at Viziadurg. Following the scheme drawn up last year at Norway, Sir Norman Lockyer hopes to take advantage of the keen sight and trained faculties of the officers and men of the ship's company to obtain observations during the forthcoming eclipse. He has asked for volunteers, and has obtained as many as 115. Unless unforeseen circumstances arise, the records obtained by this large number of observers will assist in making the eclipse memorable in the annals of astronomy.

WE regret that by an oversight the name of a distinguished Fellow of the Royal Society was not mentioned in our note on the New Year Honours. We refer to Brigade-Surgeon Lieut.-Colonel Dr. George King, who has been promoted to be a Knight Commander of the most eminent Order of the Indian Empire (K.C.I.E.). Sir George King is renowned as an Indian botanist, and for the valuable services he has rendered in connection with the introduction and cultivation of the cinchona in India. He is Superintendent of the Royal Botanical Gardens, Calcutta, and also of the Government Cinchona Plantations, Darjeeling.

AMONG the new officers of the Legion of Honour we notice the names of M. Henri de Parville, editor of *La Nature*; Dr. G. Hayem, professor in the Faculty of Medicine of the University of Paris; Dr. Raymond, professor in the same Faculty; M. Paul Buquet, director of the Central School of Arts and Manufactures; and M. Jourdan, director of the School of Higher Commercial Studies. Among the new Chevaliers of the Legion of Honour are: M. Albert Gauthier-Villars; Prof. Grouvelle, professor of industrial physics at the Central School of Arts and Manufactures; M. Leclanché, maker of electric batteries; M. Auguste Lumière, manufacturer of photographic plates; and M. Molteni, manufacturer of projection apparatus.

AT a meeting of the managers of the Royal Institution, held on January 6, Prof. E. Ray Lankester, F.R.S., was elected Fullerian Professor of Physiology in the Royal Institution.

M. VAN TIEGHEM has been elected Vice-President of the Paris Academy of Sciences for the current year, in succession to M. Wolf, who passes to the presidential fauteuil.

THE Watt Memorial Lecture, given at Greenock on the anniversary of the great engineer's birth, will this year be delivered by Prof. Thorpe. The subject will be "James Watt and the Discovery of the Composition of Water."

THE Geological Society of London will this year award its medals and funds as follows:—The Wollaston medal to Prof. F. Zirkel; the Murchison medal and part of the fund to Mr. T. F. Jamieson; the Lyell medal and part of the fund to Dr. W. Waagen; the balance of the Wollaston fund to Mr. E. J. Garwood; the balance of the Murchison fund to Miss J. Donald; the balance of the Lyell fund to Mr. Henry Woods and Mr. W. H. Shrubsole; a part of the balance of the Barlow-Jameson fund to Mr. E. Greenly.

M. LE CHATELIER has been nominated, by the Minister of Public Instruction, to the chair of Inorganic Chemistry in the College of France.

SUBSCRIPTIONS are invited for the erection of a bronze monument in honour of the eminent German chemist, August Kekulé, who established stereo-chemistry. The scheme is receiving generous support, and there is every reason for believing that a memorial worthy of Kekulé's great reputation will be erected. Friends, admirers, and old pupils who wish to assist in this object are requested to send their contributions to Dr. J. F. Holtz, Berlin N. Müllerstrasse 170-171, or to Consul J. Zuntz, Bonn Poppelsdorfer, Allee 63.

IT is announced that the German Association of Naturalists and Medical Men will hold its annual meeting this year at Leipzig, under the presidency of Prof. Waldeyer, of Berlin.

PROF. P. FRANCOTTE, assistant professor of embryology in the Université libre de Bruxelles, has been elected corresponding member of the Royal Academy of Belgium.

A PROMISING career has been cut short by the death of Dr. Hugh Calderwood, demonstrator of anatomy in the University of Glasgow.

WE notice with regret the announcement of the death of Herr Dr. Freiherr R. v. Erlanger, assistant professor of zoology at Heidelberg.

AT the Passmore Edwards Settlement, Tavistock Place, on Monday evening, January 17, Sir George Baden-Powell will lecture on the discoveries made by his expedition to Novaya Zemlya in 1896 to observe the total eclipse of the sun. He will also indicate the main points that are to be observed in India at the total eclipse of the sun on January 22.

THE death is announced of Sir Charles Hutton Gregory, K.C.M.G. He was the son of the late Dr. Olinthus Gilbert Gregory, professor of mathematics at the Royal Military Academy, Woolwich, and was born in 1817. He was a consulting engineer to the Governments of several Colonies, and a past president of the Institution of Civil Engineers.

WE are glad to learn that the new Psychological Laboratory at University College, the opening of which has been unavoidably delayed, gets to work this term. Any students who think of joining the classes should communicate at once with Dr. W. H. R. Rivers, who has charge of the laboratory during this term.

BY the death of Mr. H. Stacy Marks, R.A., the world has not only lost an eminent artist, but also an enthusiastic observer of living nature. Mr. Marks was an ornithologist who gained his knowledge of bird-life by the contemplation of his feathered friends in their natural haunts. Communion with nature gave him an insight into organic life denied to many students of comparative anatomy, and he was able to convey the knowledge to others by means of his paintings. Our readers may remember two books—"Letters to Marco" and "Riverside Letters"—consisting of collections of letters on natural history topics, sent by Mr. George Leslie, R.A., to his late friend Mr. Marks. These letters have found many sympathetic readers among outdoor naturalists. Mr. Marks was one of those who "love nature for her own sake, untrammelled by the prepossessions that not infrequently accompany that love among the votaries of science or sport." His death will be regretted by men of science as well as by artists.

THE annual general meeting of the Royal Meteorological Society will be held on Wednesday next, January 19, at 7.45 p.m., when the report of the council will be read, the election of officers and council for the ensuing year will take place, and the president (Mr. E. Mawley) will deliver an address on "Weather Influences on Farm and Garden Crops," which will be illustrated by lantern slides.

ON Tuesday next (January 18) Prof. E. Ray Lankester, F.R.S., will begin a course of eleven lectures at the Royal Institution on "The Simplest Living Things"; on Thursday (January 20) Prof. Dewar, F.R.S., will deliver the first of a course of three lectures on "The Halogen Group of Elements"; and on Saturday (January 22) Prof. Patrick Geddes will begin a course of three lectures on "Cyprus." The Friday evening meetings of the members of the Royal Institution will be resumed on January 21, when Sir John Lubbock, Bart., M.P., will deliver a discourse on "Buds and Stipules."

DR. E. SYMES THOMPSON will lecture on "Tropical Diseases," at Gresham College, Basinghall Street, on January 18, 19, 20 and 21, at 6 p.m. The lectures are free to the public.

MR. R. H. SCOTT, F.R.S., has kindly forwarded to us a note, received at the Meteorological Office, from Mr. W. T. Balmer, on a remarkable lunar corona observed at Tenby on Friday, January 7. In addition to the ordinary yellow corona, two well-defined concentric circles showing spectrum colours were seen outside it. The phenomenon was most intense at 5.35, and faded away at 5.55; the golden corona, however, was visible until about 9 p.m. The sky was cloudless, but there was a large proportion of moisture in the air; Mr. Balmer's readings for the wet and dry bulb thermometer on the morning of Friday being 37°·5 and 39° respectively.

THE German scientific weekly, *Die Natur*, commences its forty-seventh annual volume with an article on the aims of the journal by Dr. Willi Ule, who has just assumed the editorship. Dr. Ule is well known as one of the rising geographers of Germany; he has done a good deal of practical work in physical geography and in the improvement of mathematical instruments. He desires to carry out the purpose of *Die Natur*—the diffusion of a knowledge of natural science—mainly by the direct description of natural scenes and phenomena, appealing to the educated but unscientific public. The paper under its new editor promises to become an important element in the scientific culture of the German people.

REUTER'S correspondent at Paris reports that the will of the late Dr. Thomas W. Evans leaves only an insignificant sum to the direct heirs, but that, on the other hand, a sum of nearly 20,000,000 francs is bequeathed to the deceased's native city Philadelphia, contingent on the fulfilment of certain conditions of a somewhat original character. For instance, the city of Philadelphia must construct a museum which will bear the name of the Evans Museum, and in which the medals, decorations, and other insignia of the deceased, as well as his clothes, will be carefully arranged and catalogued. The city must also erect on a public square a statue of Dr. Evans, the price of which must not be less than 1,000,000 francs nor more than 2,000,000 francs.

THE next annual meeting of the British Medical Association will be held at Edinburgh on July 26–29, under the presidency of Sir Thomas Grainger Stewart, K.C.B. An address in medicine will be delivered by Dr. T. R. Fraser, F.R.S.; one in surgery by Prof. T. Annandale; and one in psychological medicine, by Sir John Batty Tuke. The following are the sections and their presidents:—Medicine, Dr. G. W. Balfour; Surgery, Dr. John Duncan; Obstetrics and Diseases of Women, Dr. A. R. Simpson; State Medicine, Sir Henry D. Littlejohn; Psychology, Dr. T. S. Clouston; Neurology, Dr. Byrom Bramwell; Pathology, Dr. W. S. Greenfield; Pharmacology and Therapeutics, Dr. J. O. Affleck; Ophthalmology, Dr. D. Argyll Robertson; Laryngology and Otology, Dr. P. MacBride; Diseases of Children, Dr. Joseph Bell; Dermatology, Dr. W. A. Jamieson; Medicine in relation to Life Insurance, Dr. C. Muirhead; Tropical Diseases, Dr. P. Manson; Anatomy, Sir John Struthers; Physiology, Dr. W. Rutherford, F.R.S.

THE ninth International Congress of Hygiene and Demography will (says the *British Medical Journal*) be held at Madrid on April 10 to April 17. The Congress is under the patronage of His Majesty Alfonso XIII. and Her Majesty the Queen Regent, and the Spanish Minister of the Interior, Señor Sagasta, is President of the Organising Committee. The Secretary-General of the Congress is Dr. Amalio Gimeno y Cabañas, Professor of Hygiene in the University of Madrid.

The President of the Executive Committee is Prof. Julian Calleja, the Vice-President the Marquis del Busto, Professor in the Madrid Faculty of Medicine. As far as relates to hygiene, the work of the Congress will be divided among ten Sections as follows: microbiology in relation to hygiene; prophylaxis and transmissible disease; medical climatology and topography; urban hygiene; hygiene of alimentation; hygiene of infancy and of schools; hygiene of exercise and labour; military and naval hygiene; veterinary hygiene, civil and military; sanitary architecture and engineering. The part of the work relating to Demography will be divided among three sections as follows: technics of demographic statistics; statistical results in relation to demography; dynamical demography (movements of population, &c.). A British Committee, of which Sir Douglas Galton, K.C.B., is Chairman, has been formed to secure the co-operation of sanitarians in this country, and generally to promote the success of the Congress. Programmes of the subjects to be dealt with, and all other particulars, may be obtained from the Honorary Secretary to the British Committee, Dr. Paul F. Moline, 42 Walton Street, Chelsea.

A CABLEGRAM through Reuter's agency, dated January 6 at Bombay, states that plague returns for Bombay show 142 cases and 105 deaths during the preceding forty-eight hours. Later news states that on January 8-9 there were 159 cases and 126 deaths. The total mortality during the present outbreak is 406. The epidemic is now following closely the lines of the original outbreak, and ominous rumours are circulating to the effect that unless things improve by the time of the forthcoming solar eclipse, there will be a serious exodus and a general suspension of business.

THE memorial presented to the Department of Woods and Forests by the Guildford Natural History Society, asking that Wolmer Forest be reserved as a sanctuary for wild birds and other animals, has been passed on to the War Department, to which the forest, including the rights of shooting and sporting, is in lease. In doing so, Mr. Howard, Commissioner of Woods and Forests, takes the occasion to remark that he is disposed to think that the best mode of arriving at the objects which the petitioners have in view is to take advantage of the game laws and the present system of game preservation in order to protect animal life generally. He thinks that where game preservation is carried out only those creatures which are specially destructive of birds are kept down, and animal life generally flourishes better than it would be likely to do in other circumstances.

DR. E. ZINTGRAFF, whose death we have already announced, was one of the most energetic of the German pioneers to whom fell the work of exploring the interior of the Cameroons, after that territory had, in 1884, become a dependency of the German Empire. Born at Dusseldorf in 1858, Dr. Zintgraff obtained his doctor's degree at the University of Heidelberg, and gained his first experience of African exploration as member of Dr. Chavanne's expedition to the Congo (1884). A year or two later he proceeded to the Cameroons, at that time a veritable *terra incognita* in respect of all but its coast line. For the space of six years his activity was unabated, and to him belongs the honour of being the first to push his way through the belt of dense forest lying behind the Coast Settlements to the open grassy plains which occupy the interior plateau, and to reach by this route the populous regions of Adamaua in the Southern Sudan, with their enterprising population of Hausas. This successful journey to the north was not made until 1889, the previous years having been occupied by detailed explorations north of the Cameroons Mountain, and by the establishment of the Barombi Station as a base from which the ultimate advance could be made. Dr. Zintgraff subsequently did much to encourage agricultural enterprise in the Cameroons. His arduous journeys had undermined his health, and the latter years of his life were spent at Teneriffe, where he died on December 5, 1897.

THE work which the late Mr. Gardiner G. Hubbard did for the cause of science is made the subject for appreciative comment in *Science*. In 1883 Mr. Hubbard and Mr. Alexander Graham Bell founded the old series of *Science*, the first editor of which was Mr. S. H. Scudder. He was what the French language terms an *entrepreneur* of scientific ideas, inventions and discoveries—the man of affairs who pushed them into the service of mankind. He was the *entrepreneur* of oral speech for the deaf, and also of the telephone, for it was through his energy and business ability that the instrument was introduced to the world and made a practical agency of intercommunication. Having accomplished this he retired to Washington, and when the National Geographic Society was founded there, he was elected first president. The function of the National Geographic Society is the discussion of the principles of geography and the diffusion of geographical knowledge among the people. To carry out this purpose Mr. Hubbard organised the *National Geographic Magazine*. Then he organised a system of bulletins designed to discuss the elements of physiography as a compendious library for teachers in the public schools, and finally he organised in the city of Washington a system of public lectures on geography, enlisting not only the members of the Society, but many other able public men in this enterprise. In all of these agencies the working geographers of Washington most heartily co-operated, and the National Geographic Society has within very few years attained remarkable influence and efficiency.

THE January number of the *National Review* has an admirable article by Mr. Gerald Arbuthnot, entitled "In Defence of the Muzzle." The temperate spirit in which it is written, and the conscientious manner in which the statistics referred to have been collected, ought to materially strengthen the hands of those who are upholding the muzzling order for dogs, in the face of the selfish and short-sighted opposition which it is receiving from a certain section of the public. In the same magazine we note also a paper by Mr. Arthur Shadwell, dealing with the recent outbreaks of typhoid fever. The writer permits himself to affirm that the medium by which the poison of typhoid fever is diffused "can hardly be anything else but water, acting directly or indirectly." The diffusion of typhoid fever is far too complicated a problem, and involves too many factors to enable water to become thus *wholly* responsible, as the writer seems to consider. Whilst contaminated water is undoubtedly an important—a very important—factor in the dissemination of this disease, there are other conditions which must be considered in this connection, and amongst such sewer-gas would seem to deserve a prominent place. Several years ago now, it was shown by an Italian investigator that the inhalation of sewer-gas markedly increased the predisposition of the subject under experiment, to suffer from the effects of typhoid poison.

IN the early days of railway engineering, little circumspection was used in laying down lines, and many tunnels were constructed which would nowadays be avoided by following the policy of evading obstacles wherever possible. An unnecessary tunnel of this kind, built fifty years ago by the North British Railway Company, and running for 3000 yards at a depth of 60 feet below the streets of Edinburgh, was afterwards discarded, another line having been constructed which carries the traffic outside the city. For a time the old tunnel remained unused, but ten years ago it was taken over by Messrs. R. and J. Paton, of Glasgow, and has since been used by them for the purpose of cultivating mushrooms. The story of this industry is briefly told in the January number of *Pearson's Magazine.* A little consideration will show that the tunnel offers ideal conditions for the growth of mushrooms; the temperature varying but very slightly, and light being absent. The result of this combination of favourable conditions is that the Scottish Mushroom Company now practically control the market in cultivated mushrooms. The Company has eight hundred mushroom beds in the tunnel, each about 12 feet by 3 feet in size. When in full operation about one thousand bushels of spawn are used yearly. The highest output reaches five thousand pounds of mushrooms per month. The steady and constant supply has killed foreign competition in mushrooms; for it appears that, whereas ten years ago the quantity of French mushrooms consumed in Great Britain largely exceeded those of home growth, they form at present only about one-hundredth part of the total supply.

A NUMBER of remarkable instances of hallucinations connected with hemianopia, or complete blindness in one or other half of the visual field, are described by Dr. W. Harris in the course of an article in the new number of *Brain.* In one case of partial hemianopia the patient had visual hallucinations, lasting a few minutes, of folk and horses moving in a reddish atmosphere, the visions being limited to the blind field of vision. Another saw continually in his blind field a man standing at the back of his head, holding two lighted candles. A man who developed right hemianopia was troubled ten days later with hallucinations of men, flies, insects, &c. At first he recognised their unreality, but after a few days he became convinced they were real. The spectres became more frequent, and he would then hunt for them in cupboards and corners. Another case of hemianopia with hallucinations in the blind field, is that of a man who suddenly lost power of speech, using wrong words, and forgetting the names of things. During a subsequent attack of temporary loss of speech he suddenly noticed while reading that his sight was confused, and that the print seemed to run together. After that he noticed he could not see so well to the right, and he used to bump up against things on his right side, and had to be careful whilst crossing the road. He also has had visual hallucinations of animals and faces moving about to his right. Dr. Harris discusses the seat of production of visual hallucinations of this kind, and concludes that they cannot be elaborated in the half-vision centre in the cuneus of the brain, but in a higher visual centre—possibly the angular gyrus.

PROF. PLATEAU'S experiments on the conditions which induce insects to visit flowers have been referred to on several occasions (see p. 179). It is worth while, however, bringing the facts together. In the concluding part of his series of papers, "Comment les fleurs attirent les insectes," in the *Bull. de l'Acad. des Sciences de Belgique*, Prof. Plateau thus sums up the results at which he has arrived. In seeking for pollen or nectar, insects are guided only to a subsidiary extent by the sense of sight. They continue to visit scented flowers after the coloured parts have been almost entirely removed. When flowers of the same species vary in colour, they exhibit neither preference nor antipathy for one colour over another. Inconspicuous flowers hidden among foliage attract large numbers of insects. Artificial flowers made of paper or calico, even when brightly coloured and closely resembling real flowers, are not visited by insects; but they are when made of green leaves which have a vegetable scent. If flowers which have little or no nectar, and which are therefore habitually neglected by insects, are smeared with honey, insects are attracted in large numbers. On the other hand, if the nectary is removed from flowers habitually visited, their visits cease at once. The author has paid especial attention to entomophilous flowers, and finds that their exemption from the visits of insects is due mainly to their not providing them with honey. From all these facts M. Plateau draws the conclusion that the guiding sense to insects in visiting flowers must be chiefly the sense of smell.

WRITING in the *Revue générale des Sciences* for December 30, 1897, Dr. Louis Olivier describes the latest combination of the principles of the microphone and phonograph under the name of *microphonograph*, the invention of M. F. Dussaud, of Geneva, and which has been subsequently developed by M. George F. Jaubert and M. Berthon. A demonstration of the properties of this apparatus was given a short time ago at the house of M. and Mme. Eugène Pereire. From certain physiological facts, Dr. Laborde showed the possibility of rendering sounds audible to deaf mutes by this instrument, and his view received practical confirmation at the hands of Dr. Gellé, who experimented with signal success on a number of subjects to whom a sensation of sound was thus conveyed for the first time. It is suggested that the micro-phonograph may become an important factor in the education of deaf and dumb subjects. It will be remembered that a method of giving deaf mutes the feeling, or at all events the rhythm of music, was devised by Prof. McKendrick, and has been described in these columns (vol. lvi. p. 212). Finally, M. Berthon and M. Jaubert have employed the new apparatus in connection with the telephone and the kinematograph, the latter combination rendering it possible to reproduce scenes with all the attendant sounds of conversation and so forth. With this apparatus it is proposed to arrange life-like reproductions of a number of naval scenes at the Exhibition of 1900, under the auspices of the Compagnie générale Transatlantique.

WHERE certain salts, such as bromide of potassium and chloride of sodium, undergo changes of colour under the action of kathodic rays, after the method of Goldstein, it has been found by Profs. Elster and Geitel that they are at the same time rendered photo-electrically sensitive, inasmuch as in sunlight or broad daylight they lose any negative electric charges imparted to them more rapidly than in the dark. The same physicists, writing in *Wiedemann's Annalen* (62), now examine whether the same property is conferred on these salts when the coloration is produced by heating them in the presence of potassium or sodium vapour, after the manner described by Kreutz and Giesel. In the case of common salt, the electrometer readings representing the loss of charge in one minute in light were as follows:—For salt coloured by kathodic rays and kept in darkness a year, 214; rock-salt coloured brown to blue by potassium vapour, 73; natural violet salt, 23; chloride of sodium coloured by Berlin blue, + 1; the corresponding data in the dark being 0, − 10, − 2, − 3. With potassium bromide, nearly blackened by potassium vapour, in light, 171; the same bright blue, 101; the same coloured by Berlin blue, + 1; the results in darkness being − 4, + 2, 0 −. There is thus no doubt that the same photo-electric properties are conferred on the salts by potassium vapour as by kathodic rays; and, moreover, these properties exist more or less in the natural violet and blue varieties of such minerals as rock-salt and fluor-spar.

A DETAILED account of experiments in gliding flight is contributed by Mr. Octave Chanute to the *Journal of the Western Society of Engineers* (U.S.A.) for 1897. After trying many different types of gliding machines, some with as many as six superposed pairs of wings, Mr. Chanute seems to have chosen for his later experiments a form of apparatus with two narrow superposed aëro-curves of rectangular form. The most noteworthy feature of Mr. Chanute's investigations is his invention of a regulating mechanism by which the fore and aft equilibrium and stability is automatically maintained without any exertion or special agility on the part of the operator, and even the action of side gusts of wind is considerably diminished. We observe that the wing surfaces are fixed above the operator's head, an arrangement quite the reverse of that adopted by Mr. Pilcher. Nevertheless both Mr. Chanute and Mr. Herring have made numerous glides with perfect safety, and the latter has achieved considerable success in "quartering," *i.e.* advancing at an angle with the wind along the side of a hill up which a current of wind is blowing. By this means Mr. Herring has succeeded in making a glide of 927 feet, the time occupied being about forty-eight seconds.

THE *Bulletin* of the Italian Geographical Society publishes a note announcing the successful starting from Tabriz of a small scientific expedition to Lake Urmia, under the direction of Prof. Paladini of Milan. It is intended to make a survey of the lake and the region immediately surrounding it.

APPLYING the principles laid down by Penck, in his "Morphologie," to the excellent and abundant data published by Forel, Dr. Wilhelm Halbfass has worked out in detail the morphometry of the Lake of Geneva: the results are to be found in the *Zeitschrift der Gesellschaft für Erdkunde zu Berlin* (vol. xxxii. No. 4).

THE greater part of Nos. 9 and 10 of the present volume of the *Mittheilungen* of the Vienna Geographical Society is devoted to a learned paper, by Herr Fritz Pichler, on the Noreia of Polybius and of Castorius. Herr Pichler concludes that the town called Noreia by Castorius, near Neumarkt in Upper Styria, is an unimportant station, of which there is no trace previous to 365 A.D. The real Noreia of Polybius is the same as Virunum, near Klagenfurt, Noreia being the older name, traceable from B.C. 113 for centuries backwards.

MESSRS. SWAN SONNENSCHEIN AND CO. announce that they will shortly publish a work, entitled "The Wonderful Century: its Successes and its Failures," by Dr. Alfred R. Wallace, F.R.S. The object of the volume is to give a short descriptive sketch of all the more important mechanical inventions and scientific discoveries which are distinctive of the nineteenth century, and especially to enable those, who have lived only in the latter half of it, to realise its full significance in the history of human progress. The author maintains that our century is altogether unique; that it differs from the eighteenth or seventeenth centuries, not merely as those differed from the centuries which immediately preceded them, but that it has initiated a new era, and that it may be more properly compared with the whole preceding historical period.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Miss Vine; an Egyptian Jerboa (*Dipus ægyptius*) from North Africa, presented by Mr. H. W. Wibrow; an Indian Python (*Python molurus*) from India, presented by Mr. F. J. Allpress; three Common Squirrels (*Sciurus vulgaris*), British; two Blue-faced Honey-eaters (*Entomyza cyanotis*) from Australia, a Razorbill (*Alca torda*), two Common Widgeon (*Mareca penelope*), twelve Common Teal (*Querquedula crecca*), European, purchased.

OUR ASTRONOMICAL COLUMN.

COMPANIONS TO VEGA.—One of the proofs given as to the light-gathering power of the new Yerkes telescope is that Prof. Barnard has observed a new companion to Vega, which even the Lick telescope had failed to make visible. Measures made with a temporary micrometer gave its position angle 312° and distance 53″ with respect to Vega. It is said to be much fainter than the small star discovered by Winnecke at Pulkova in 1864, whose magnitude is 14·5. In the *Astr. Journ.* (No. 414) Prof. Barnard points out that the latter companion, with position angle 288°·9 and distance 53″, is the same as that discovered by Mr. George Anderson, of the United States Naval Observatory, in 1881, but with a slightly modified position.

HARVARD COLLEGE REPORT.—In the fifty-second "Annual Report of the Astronomical Observatory of Harvard College," Prof. Pickering gives an interesting account of the work done. As regards buildings his report is similar to that from many other observatories, in that they are old and far behind observatories not only of the first rank, but even of the second class. On the other hand, however, very few can say with him "that their strongest feature is the large endowment for current expenses, which enables the large staff of forty assistants to be employed." The excellent work done at Arequipa is described in another part of NATURE (p. 249), so we will content ourselves with a brief summary of the work done in other sections of the observatory.

As before, Mr. O. C. Wendell has been engaged in the observations of variable stars, and the number of measures made is almost astounding, *e.g.* 1031 comparisons of ο Ceti, 3296 of U Cephei, &c. Another series of interesting photometric comparisons are those made by Mr. E. R. Cram, on β Lyræ, the total number of measures being 2304.

With the "Meridian Photometer" the total number of photometric settings has surpassed all previous records, numbering 100,052, and observations of all the stars of magnitude 7·5 and brighter, and north of − 40°, are now nearly completed. Besides star work, measures were made of Uranus, Neptune, and nearly 500 each of Ceres, Juno, and Vesta.

The work in connection with the Draper Memorial has also been remarkable, and the hydrogen lines have been shown to be bright in the spectra of many known variables, U Cassiopeiæ, R Piscium, R Canis Minoris, and many others; also new variable stars have been detected by means of bright hydrogen lines in their spectra. The Report shows that excellent results have been attained; and such, we know, is the case from notes of discoveries made at the observatory, announcements of which have appeared from time to time in these columns.

ARTHUR KAMMERMANN.—We regret to record the death of Arthur Kammermann, astronomer at the Geneva Observatory (*Astr. Nach.*, No. 3469).

Born at Bienne in 1861, he received his higher education at the Zürich Polytechnic, leaving there in 1881 with the diploma of "Fachlehrer." At Zürich he was initiated into astronomical work by M. R. Wolf, who strongly recommended him to Plantamour, at Geneva Observatory, where he became attached as assistant.

After the retirement of Dr. W. Meyer in 1883, he had the Plantamour equatorial under his charge, and undertook astronomical photography with it; with this instrument he worked until his death, and many of his observations have been published in the *Astr. Nach.* He was largely occupied with meteorological matters; and in the chronometric work of the observatory he rendered great services which benefited the watchmaking industry, so important to Geneva.

MINOR PLANETS IN 1897.—The total number of minor planets discovered in 1897 was only eight, which is considerably below the average of recent years; so that perhaps in time we shall be able to obtain a complete list of them. The latest discoveries were those of Charlois at Nice: DL on November 23, DM, DN, DO on December 18.

WE have received from Mr. Arthur Mee a copy of his "Amateur Observer's Card Almanac." The calendar brings together in a handy form the principal phenomena for each day in the year, and it will be found useful to hang upon the walls of the observatory for reference.

PROF. G. M. SEARLE, professor of mathematics and astronomy in the Catholic University of America, has been appointed by the Pope to succeed the late Father Denza as director of the Vatican Observatory.

Science states that money has been granted by the Trustees of Amherst College for the purchase of a new telescope to replace the old instrument in use at present, and the bequest of 18,000 dollars for the purchase of a site for a new observatory will be expended as soon as the various plans for a new position have been carefully considered.

EARLY MAN IN SCOTLAND.[1]

II.

ONE may now inquire into the reason why cinerary urns, with their contained ashes, and short cists, enclosing bodies which had been buried in a bent or stooping attitude, should be associated with the men of the Bronze Age. The first and most important is the presence of objects made of bronze. In the 144 localities under analysis in which interments ascribed to the Bronze Age have been examined, bronze articles were found in thirty-four directly associated with the interments. In four of these the bronze was along with objects made of gold. In seven other interments of the same character gold ornaments without bronze were present. The men of this period were, therefore, workers in gold also; and as it has been, and indeed still can be, mined in Scotland, it is not unlikely that the ornaments had been wrought from native metal. Additional proof that the burials in short cists, and after cremation in cinerary urns, both belonged to the same period, and were practised by the same people, is furnished by the presence of articles of bronze and gold in both groups of interment.

But, in addition to metallic objects, the graves sometimes contained other implements and ornaments. In many localities articles made of flint, stone, or bone, and jet beads were associated with bronze. In others flints in the form of chips, knives, arrow-heads, and spear-heads; stone implements in the form of whetstones and hammers; bone and jet ornaments and bone pins have been found in short cists, and some of these articles also in cremation interments, unaccompanied by bronze.

Attention has been called by Dr. Joseph Anderson to the character of the bronze objects usually associated with these burials ("Scotland in Pagan Times"). For the most part they have been thin blades, leaf-like or triangular in form, and either with or without a tang for the attachment of a handle. From their shape they might have been used as spear-heads, daggers, or knives. Not unfrequently the surfaces of the blade were ornamented with a punctuated or incised pattern. Sometimes bronze pins, rings and bracelets have been obtained from these interments. It should, however, be stated that the bronze articles and ornaments of gold found in association with the burials are of a more simple character, and present less variety in form, purpose and decoration than those which have been got in hoards, in various parts of Scotland. It would seem, therefore, as if the people of this period, even if they were in possession of such finished and beautifully decorated swords, bucklers, axes and bronze vessels as have been got in the hoards just referred to, did not deposit them in the graves of their deceased friends and relatives. It may be, however, that the simpler articles found in the interments represent a period in the Bronze Age earlier than that in which the art of making the more elaborate articles had been acquired, when perhaps the custom of depositing grave goods had been more or less departed from.

Cinerary urns are not the only utensils formed of baked clay to which the term urn has been applied, and archæologists recognise by the names of "incense cups," "food vessels" and "drinking cups," three other varieties.

The examples of so-called Incense cups are not numerous in Scotland; they were associated with cremation interments, and have usually been contained in cinerary urns; they are the smallest of all the varieties of urn, and are, as a rule, from 2 to 3 inches high and about 3 inches wide. In one specimen from Genoch, Ayrshire, the cup possessed a movable lid. Not unfrequently the outer surface was patterned with horizontal, vertical, and zig-zag arrangements of lines. In a few cases the sides were perforated, as if to allow the escape of fumes; and it is probably from this character, as well as from their small size, which fitted them for being easily carried in the hand, that they have been termed incense cups. The burning of incense would, however, imply, on the part of the people of the Bronze Age, the possession of fragrant gums and resins such as are not indigenous to Britain, and which the ancient Caledonians were not at all likely to be in a position to procure. In most instances the contents of these cups were not preserved by the finders. An example which was discovered in 1857 at Craig Dhu, North Queensferry, covered by a larger urn, and about the size of a teacup, was filled with calcined human bones; the specimen from Genoch, found a number of years ago by Dr. James Macdonald, of Ayr, contained the burned bones and ashes of a child in its fifth or sixth year. Of the conflicting theories as to the purpose to which these cups were applied, the view that, like the large urns with which they were associated, they were cinerary, and were intended for the reception of the ashes of an infant or young child, seems the most probable.

Numerous examples of the variety of urn termed "food vessel" have been found in Scotland, and "drinking cups" although not quite so numerous, are fairly represented. In the 144 localities under analysis, the bowl-shaped food urns were found in thirty-one, drinking cups in twenty-five, and in seven instances the size and form of the urn is not stated with sufficient precision. With a few exceptions, in which the character of the burial had not been fully described, the urns were contained in short cists, in which also the skeleton of an unburnt body in the bent or contracted position was lying. In several instances it is stated that the urn, either food or drinking vessel, contained black dust, or earth, or greasy matter, but burnt bones are never said to constitute their contents. Not unfrequently, although this is not an invariable rule, the urn was placed in proximity to the head and raised hands of the skeleton.

These varieties of urn are by no means invariably present in short cists. In twenty-five localities where this kind of grave was seen, there is no record of either form of urn being present. It is obvious therefore that, though associated with so many inhumation interments, they were not regarded as necessary accompaniments, and they obviously discharged in the minds of the people of the time a different function from that of cinerary urns. The term food-urns applied to the bowl-shaped variety is probably appropriate, as indicating that edible substances were placed in them, in the belief that food should be provided for the use of the corpse. It is questionable, however, if the taller variety were drinking cups, as the unglazed clay would not fit them for the retention of liquids for any length of time. The presence of food urns in cists, along with, in some instances, implements and weapons, would point to the belief, in the minds of those practising this form of interment, in a resurrection of the body, and a restoration to the wants and habits of the previous life. It may be that placing the body in the crouching position, lying on one side, was regarded as the attitude best fitted, when the proper time came, to enable it to spring into the erect position and assume an active state of existence. The practice of cremation, however, to an almost equal extent as inhumation, by people of the same period, shows that they may not all have shared in the belief in a corporeal resurrection. But it should not be forgotten that, even in many cremation interments, blades and other objects made of bronze have been found along with the burnt bones and cinerary urns, as if for use in a future life.

The association of bronze objects, both with short cists and cinerary urns, establishes these forms of interment as practised at a time when bronze was the characteristic metal used in many purposes of life. The crouching attitude of the dead body, the contracted grave, and the varieties of urns already described, are therefore to be regarded as equally characteristic of this period, even if bronze is not found in a particular instance associated with the interment, and this view is generally held by archæologists in Scotland.

In a preceding paragraph implements and weapons made of stone, flint and bone were referred to as having been sometimes associated with bronze, and also of similar objects having been found in graves, in which, though obviously of the same class and period, no article made of metal was observed. Such an association proves that there was no sharp line of demarcation between the employment of the more simple substances used by Neolithic man in the manufacture of implements and weapons, and the use of bronze for similar purposes. The two periods undoubtedly overlapped. It has been customary to regard this overlapping as if bronze-using man had continued for a period, to employ the same substances in making useful articles as did his Neolithic predecessors; that time was required before the more costly bronze, imported from foreign sources, replaced the native material, and that consequently both groups of objects became associated in the same grave.

Additional light is thrown on the mixture in the same interment of objects representing different stages of culture by a collection of goods from the grave of an aboriginal Australian, buried about fifty years ago, recently brought under my notice by Dr. R. Broom. Along with the skeleton were found a clay pipe, an iron spoon, the remains of a rusted pannikin, the handle of a pocket-knife, and a large piece of flint. The handle of the knife, with its steel back, had doubtless been used along with the flint for the purpose of obtaining fire, as in Neolithic times a similar office was discharged by flint and a nodule of pyrites. These accompaniments of the Australian interments show that men in a lower grade of culture and intellectual power utilise, as opportunity offers, objects representing a much higher civilisation. It is possible, therefore, that some of the mixed interments ascribed to the Bronze Age may be the graves of Neolithic men who, in conjunction with articles of their own manufacture, had employed the material introduced by a bronze-using race, with whom they had been brought in contact, and whose usages they had more or less imitated.

---

[1] A discourse delivered at the Royal Institution, London, by Sir William Turner, F.R.S. (Continued from page 237.)

That the inhabitants of prehistoric Scotland were not a homogeneous people, but exhibited different types in their physical configuration, so as to justify the conclusion that they were not all of the same race, has long been accepted by archæologists. The first observer who made a definite statement, based on anatomical data, was the late Sir Daniel Wilson, in his well-known "Prehistoric Annals of Scotland." Whilst admitting that the material at his disposal was scanty, he thought that he was justified in stating that the primitive race in Scotland possessed an elongated dolichocephalic head, which he termed boat-shaped, or kumbecephalic. This race, he said, was succeeded by a people with shorter and wider skulls, which possessed brachycephalic proportions. Further, he considered that both these races preceded the intrusion of the Celtæ into Scotland. But the evidence is by no means satisfactory that the interments from which Wilson obtained the long kumbecephalic skulls were of an older date than those which yielded the brachycephalic specimens. So far, therefore, as rests upon these data, one cannot consider it as proved that a long-headed race preceded a broad-headed race in Scotland, and that both were antecedent to the Celtæ.

Evidence from other quarters must be looked for, especially from the extensive researches of Thurnam, Greenwell, Rolleston and other archæologists into prehistoric interments in England; and by the study of the material which has accumulated in Scotland since the publication of Sir Daniel Wilson's "Prehistoric Annals."

The remains of prehistoric man in England subsequent to the Palæolithic Age have for the most part been found in mounds and tumuli, some of which were very elongated in form, others more rounded, so that they have been divided into the two groups of Long and Round barrows. There is a consensus of opinion that the long barrows were constructed by a race which inhabited England prior to the construction of the round barrows. The long barrows are indeed the most ancient sepulchral monuments in South Britain; obviously they were erected before the use of bronze or other metal became known to the people. They belonged, therefore, to the Neolithic Age, as is testified by the implements and weapons found in them being formed of stone, flint, bone and horn, and by the absence of metals. They are not widely distributed in England, but are found especially in a few counties in the north, as Yorkshire and Westmorland, and in the western counties in the south. The builders of these barrows in their interments practised both inhumation and cremation, but the burnt bones were never found in urns.

The study of the human remains obtained from the English long barrows by Drs. Thurnam and Rolleston proves that the crania were distinctly dolichocephalic, and that the height was greater than the breadth. Those measured by Dr. Thurnam gave a mean length-breadth index 71·4, whilst Dr. Rolleston's series were 72·6.

The round barrows were constructed by a bronze-using people. The crania obtained in them were, as a rule, brachycephalic. Of twenty-five skulls measured by Dr. Thurnam seventeen had the length-breadth index 80 and upwards, and in six of these the index was 85 and upwards. Only four were dolichocephalic, whilst in three the index ranged from 77 to 79. In the brachycephalic skulls the height was less than the breadth.

As similar physical conditions prevailed both in England and Scotland during the Polished Stone and Bronze periods, there is a strong presumption that the two races had, in succession to each other, migrated from South to North Britain. Unfortunately very few skulls have been preserved which can with certainty be ascribed to Neolithic man in Scotland, but those that have been examined from Papa Westray, the cairn of Get and Oban, are dolichocephalic, and doubtless of the same race as the builders of the English long barrows.

Seventeen skulls from interments belonging to the Bronze period have been examined by the author. The mean length-breadth index of twelve was 81·4, and the highest index was 88·6. In each skull the height was less than the breadth. In the other five specimens the mean index was 74; the majority, therefore, were brachycephalic. In only one specimen was the jaw prognathic; the nose was almost always long and narrow: the upper border of the orbit was, as a rule, thickened, and the height of the orbit was materially less than the width. The capacity of the cranium in three men ranged from 1380 to 1555 c.c.; the mean being 1462 c.c. In stature the Bronze men were somewhat taller than Neolithic men. The thigh bones of the Bronze Age skeletons gave a mean platymeric index 75·1, materially below the average of 81 8 obtained by Dr. Hepburn from measurements of the femora of modern Scots.[1] The tibiæ of the same skeletons gave a mean platyknemic index 68·3; intermediate, therefore, between their Neolithic predecessors and the present inhabitants of Britain. Many of the tibiæ also possessed a retroverted direction of the head of the bone; but the plane of the condylar articular surfaces was not thereby affected, so that the backward direction of the head exercised no adverse influence on the assumption of the erect attitude.

Whilst in England the Bronze Age round barrows are numerous and the burials in short cists are comparatively rare, in Scotland the opposite prevails. Whilst part of Dr. Thurnam's aphorism, viz. "long barrows, long skulls," applies to both countries, the remaining part, "short barrows, short skulls," should be modified in Scotland to "short cists, short or round skulls."

The presence of dolichocephalic skulls in the interments of the Bronze Age shows that the Neolithic people had commingled with the brachycephalic race. Similarly the Bronze men, though subject to successive invasions by Romans, Angles, and Scandinavians, have persisted as a constituent element of the people of Great Britain. The author has found a strong brachycephalic admixture in the crania of modern Scots, in Fife, the Lothians, Peebles, and as far north as Shetland. In 116 specimens measured, 29, *i.e.* one-quarter, had a length-breadth index 80 and upwards, and in five of these the index was more than 85.

The question has been much discussed whether the people of the Polished Stone Age were descended from the men of the Ruder Stone Age, or were separated from them by a distinct interval of time. The latter view has been supported by Prof. Boyd Dawkins, who contends that there is a great zoological break between the fauna of the Palæolithic, Pleistocene period and that of the Neolithic Age, and that the two periods are separated from each other by a revolution in climate, geography and animal life.[2]

Undoubtedly many large characteristic mammals of the Palæolithic fauna had entirely disappeared from Britain and western Europe, but some nine or ten species, as the otter, wolf, wild cat, wild boar, stag, roe, urus and horse, were continued into the Neolithic period; at which time the dog, small ox, pig, goat, and perhaps the sheep, as is shown by their osseous remains, were also naturalised in Britain. The continuity of our island with the continent by intermediate land, which existed during Palæolithic times, also became severed, and a genial temperate climate replaced more or less arctic conditions.

Man, however, possesses a power of accommodation, and of adapting himself to changes in his environment, such as is not possessed by a mere animal. The locus of an animal is regulated by the climate and the nature of the food, so that a change of climate, which would destroy the special food on which an animal lives, would lead to the extinction of the animal in that locality. Man, on the other hand, is omnivorous, and can sustain himself alike on the flesh of seals, whales and bears in the Arctic circle, and on the fruits which ripen under a tropical sun. Man can produce fire to cook his food and to protect himself from cold, and can also manufacture clothing when necessary. Palæolithic man has left evidence that he had the capability to improve, for the cave men were undoubtedly in advance of the men who made the flint implements found in the river drifts. The capacity of the few crania of Palæolithic man which have been preserved is quite equal to, and in some cases superior to that of modern savages. So far as regards the implements which he manufactured and employed, Neolithic man showed *no* material advance over the Palæolithic cave dweller.

---

[1] *Journal of Anat. and Phys.*, October 1896, vol. xxxi.

[2] "Cave Hunting, and *Journal* of Anthropological Institute," vol. xxiii., February 1894.

The association of the bones of domestic mammals, which were not present in Palæolithic strata, along with the remains of Neolithic man, proves that additional species had been introduced into Western Europe at a particular period, probably by another race which had migrated northward and westward; but it by no means follows that Palæolithic man had of necessity disappeared prior to this migration, and that when Neolithic man reached Western Europe he found it, as regards his own species, a desolate solitude. How then did Neolithic man with his associated animals find his way into Britain?

Was it whilst the land remained, which connected Britain with the continent in interglacial times, and along which Palæolithic man had travelled, or was it at some subsequent period after the formation of intermediate arms of the sea? If the latter, then the further question arises, How was the transit effected? Neolithic man, so far as is known, had no other means of conveyance by water than was afforded by a canoe dug out of the stem of a tree. Although such rude boats might in calm weather serve as the means of transporting a few individuals at one time across a river or narrow strait from one shore to the other, they can scarcely be regarded as fitted for an extensive migration of people; still less as a means of conveying their pigs, dogs, goats and oxen. Hence one is led to the hypothesis that, after the sea had submerged the intermediate land of interglacial times, there had been a subsequent elevation so that Britain again became a part of the continent of Europe. If one may use the expression, a "Neolithic land bridge" was produced, continental relations and climate were for a time re-established, and a free immigration of Neolithic man with his domestic animals became possible. This may have been at the period when an abundant forest growth in Scotland succeeded the elevation of what is now called the 100-foot terrace. There is no evidence of the presence of Neolithic man in Scotland until about that period. Before this island with its surrounding and protecting "silver streak" settled down to the present distribution of land and water, there are ample data, as is shown by the three sea beaches at different levels seen so distinctly on the coast of Scotland, that frequent oscillations changed the relative positions of land and sea to each other.

From the consideration of what may be called the biological data, the conclusion seems not to be justified, that because climatic changes had led to a disappearance of certain characteristic Palæolithic mammals, but by no means of all, therefore Palæolithic man had vanished along with them. When Neolithic man reached Western Europe, he in all likelihood found his Palæolithic predecessor settled there, and a greater or less degree of fusion took place between them. Hence, as the present inhabitants of Britain may claim the men both of the Neolithic and Bronze Ages as their ancestors, it is possible that as Neolithic man migrated northward into Scotland he may have carried with him a strain of Palæolithic blood. W. T.

PROGRESS OF TECHNICAL EDUCATION.

A REVIEW of the progress of technical education in the United Kingdom during the year 1896-97 is given in the tenth annual report of the National Association for the Promotion of Technical and Secondary Education. A general idea of the present position of the technical education movement may be obtained from the subjoined extracts from the report just issued.

Technical Education in England.

It is pleasing to be able to record that, in the year 1896-97, the total amount of money available under the Local Taxation (Customs and Excise) Act, 1890, and distributed to the local authorities, was larger than in any previous year, and that a further advance has been made as regards its utilisation for educational purposes.

Of the 49 County Councils in England 41 are now giving all and eight are giving part of their grants to educational purposes, while of the 61 County Borough Councils 55 are devoting all and six are devoting part of the fund in a like manner. In the county borough of Preston a noteworthy advance has been made. In this locality a new technical institute, erected by the Harris Trustees at a cost of about 20,000*l.*, has recently been opened, and the County Borough Council, by voting a sum of 500*l.* in aid of technical education in the borough, have now retired from that position of isolation which they had hitherto occupied. At the present time, therefore, all the County and County Borough Councils in England are utilising the provisions of the Technical Instruction Acts.

In considering the amount of money devoted one way and another, it may be stated that, of the total of 807,000*l.* now available in England alone, no less a sum than 740,000*l.* is being spent upon education. It is worthy of note that London's share of the fund now reaches 185,000*l.*, of which a sum of 150,000*l.* is being utilised for educational purposes, a growth of 30,000*l.* as compared with last year's vote. Therefore, looking at the position as a whole, it is clear that education continues to receive financial support of an extending character.

In last year's report particulars were given respecting local authorities contributing funds to education in the form of *rate aid*. The information then published went to show that there were at least 137 localities providing a total sum of 34,000*l.* in this manner. To these figures must now be added a further 23 authorities raising 5000*l.*, thus making an aggregate number of 160 local authorities levying rates, or voting lump sums from the rate-fund, to the extent of 39,000*l.*

The extent to which local authorities and responsible committees in England have built, or are building, or are about to build, technical schools is shown by the fact that the number of such schools thus initiated now reaches 161, of which 146 involve a capital expenditure of 1,730,000*l.* This sum is *exclusive* of about 500,000*l.* absorbed by the establishment of polytechnic institutions in London. It is worthy of notice that in Burslem, Chesterfield, Dewsbury, Keighley, Plymouth, Rochdale, Southport and Walsall the necessary funds for building purposes were provided entirely by voluntary contributions, and that in Lancaster, Northwich, St. Helens, Sandbach and Winsford sites and technical schools have been presented to the local authorities by private individuals; it may be estimated that, with the exception of Lancaster and Sandbach, concerning which complete information is not available, the financial provision which has thus been made in eleven localities represents a total of 137,000*l.* Of the aggregate number of technical schools mentioned above, 100 are already at work, 26 new schools, situate in 13 different counties, having been opened during the past year; the localities in which the largest of these new schools are to be found and the amounts spent upon the buildings are—Leicester (40,000*l.*), Preston (20,000*l.*), Darlington (16,000*l.*), Oldham and West Hartlepool (15,000*l.* each), Darwen (14,000*l.*), Swindon (13,000*l.*), and Handsworth and Northwich (10,000*l.* each). There remain, therefore, 61 technical schools which, according to the latest information, are still incomplete; but it must be understood that this number includes localities where technical schools have been transferred to the local authorities and where new schools are also being built.

In Bradford the technical college, upon which has been spent no less than 155,000*l.* (50,000*l.* for buildings and 105,000*l.* for maintenance), mainly provided by private munificence, now receives an annual grant of 2875*l.* from the Corporation; in Huddersfield, the Governing Body of the technical college have recently decided to proceed with considerable extensions to the present buildings at an expenditure, including the cost of furnishing, of 12,000*l.*; in Keighley, the mechanics' institution was founded in 1825, a new building, costing nearly 20,000*l.*, was erected by public subscription in 1870, and an additional wing was built, at an outlay of 11,000*l.*, in 1887. Hitherto there has been but one instance of a local authority divesting themselves of their powers of direct control, namely that of Burnley, where the County Borough Council, having established a technical school at a cost of 4000*l.*, transferred the management of the same to the Committee of the local mechanics' institution, the Committee receiving an annual grant of 1000*l.* from the Council.

During the year ended March 31, 1896, the expenditure, excluding capital outlay, upon agricultural education by thirty-six County Councils in England reached a total sum of 58,349*l.*

According to the latest annual report of the Board of Agriculture, the amount of money applied to this branch of technical education by the County Councils of England (including Monmouthshire, but excluding Derbyshire, the Soke of Peterborough and the Southern Division of Buckinghamshire) during the year 1896-97 was estimated to be 78,000*l.*, which sum includes capital expenditure.

Progress in Wales.

The whole of the sum of 38,000*l.* available under the Local Taxation (Customs and Excise) Act, 1890, is devoted to the purposes of intermediate and technical education, together with an estimated sum of 20,000*l.* raised by rate under the Technical Instruction Acts, 1889 and 1891. In addition to these sums, an amount of over 17,000*l.* is raised under the provisions of the Welsh Intermediate Education Act, 1889, which sum is met by a contribution from the Treasury not exceeding the amount payable out of the county rate, and based upon the efficiency of the schools aided by the local authorities. The total sum which is annually appropriated to intermediate and technical education in Wales is, therefore, about 92,000*l.*

In Cardiff, by an agreement between the Corporation and the University College of South Wales and Monmouthshire, the entire responsibility of providing technical instruction is placed upon the college, in consideration of a large annual grant, together with all fees and grants earned by, or on behalf of, the students. The work of the college in this connection comprises the maintenance of a large number of evening science and art and technical classes, a women's technical department, and a higher technical department, and the establishment of scholarships and studentships.

Expenditure on Technical Education in Scotland.

Of the total amount of 39,000*l.* distributed to local authorities under the Local Taxation (Customs and Excise) Act, 1890, an estimated sum of 28,000*l.* is devoted to technical and secondary education. This, with the addition of an amount of 60,000*l.* available under the provisions of Section 2 of the Education and Local Taxation Account (Scotland) Act, 1892, makes the total sum devoted to technical and secondary education in Scotland 88,000*l.*, excluding those sums which are applied to technical education by six School Boards out of the school fund under the Technical Schools (Scotland) Act, 1887.

The Position of Ireland.

The year 1897 has been one of disappointment to those interested in technical education in Ireland. In February a large and representative deputation, organised by the Technical Education Association for Ireland, waited upon the Lord-Lieutenant. His Excellency, who was much impressed by the influential character of the deputation, and the arguments which they advanced, announced that it was the intention of the Government to introduce a Bill in the coming session which would deal with agricultural instruction, and promised to use his influence with his colleagues to introduce a Bill dealing with technical education at the earliest possible opportunity.

This promise was fulfilled, for not only was a Bill introduced to create a Board of Agriculture and Industries for Ireland, but provision was made in the Budget for an endowment of technical education. But the hopes, which the action of the Government raised, were doomed to disappointment. The Agriculture and Industries (Ireland) Bill, being unfavourably received by the Irish Members of Parliament owing to its financial clauses, was withdrawn; an announcement was made by the First Lord of the Treasury that as an alternative policy a Local Government Bill would be introduced during the following session, and the provision made in the Budget for technical education was otherwise appropriated.

At the end of November a still larger and more representative deputation, organised by the Dublin Chamber of Commerce, and representing all the Chambers of Commerce, the principal municipalities, and the leading agricultural and industrial organisations of Ireland, waited on the Chief Secretary for Ireland and pressed upon the Government the need of establishing a Board of Agriculture and Industries during the forthcoming session. The strongest representations were made as to the urgency of the matter. But the Chief Secretary, though admitting the urgency, informed the deputation that the Government were pledged to the Local Government Bill, and that it would not be fair to buoy up those interested in the movement with the hope that there was any reasonable prospect that the Government would be able to deal with two first-class Irish measures in the one session. The encouraging feature about the situation is that public opinion is thoroughly aroused upon this question, and there is, therefore, no fear that the matter will be allowed to drop.

Early in the year the Lord-Lieutenant appointed a Commission to "inquire and report with a view to determining how far, and in what form, manual and practical instruction should be included in the educational system of primary schools under the Board of National Education in Ireland." The Commission have held sittings in the principal Irish towns, as well as in England and in Scotland, and have sent experts to report upon the position of manual and practical instruction in connection with elementary education in Germany and France. It is expected that their report will be submitted to the Lord-Lieutenant sufficiently early in the year to allow the Government to make provision in the estimates to carry out the recommendations of the Commission.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Prof. G. Krause, of Halle, has been appointed ordinary professor of botany to the University of Würzburg, in the place of the late Prof. J. Sachs.

Among the measures to be laid before the Prussian Diet during the session opened on Tuesday is one on the vexed subject of disciplinary procedure against University Lecturers. In the Speech from the Throne this is alluded to as a "legislative regulation of the circumstances concerning the position of University lecturers."

The Duchess of Fife opened the new Municipal Technical School at Brighton on Saturday last. The Duke of Fife, replying on behalf of the Duchess to a vote of thanks passed to her Royal Highness, remarked that in establishing the school Brighton had placed itself in line with all the great centres of population in the country, and showed itself alive to the great educational necessity of the day.

Speaking at the annual dinner of the Yorkshire College, Leeds, on Friday last, Lord Londonderry said that England was only slowly waking up to the fact that a technical, as distinguished from a commercial or literary, education was becoming more and more essential every day. A great deal had been done by the Yorkshire College, which had to deal with a county vast in its dimensions, and containing within its limits every variety of trade industries. The College had come to the assistance of all these industries. It had rendered valuable assistance to dyeing and weaving as well as to the application of art to the textile industries, and thanks to the grant by the Clothworkers' Company of 50,000*l.* for the establishment of this department, no less than 2500*l.* a year was expended to make the College the first weaving and dyeing school in the country. Many more such institutions as the Yorkshire College are needed before technical education is sufficiently provided for the needs and requirements of the country.

Teachers of science and science classes in higher-grade and public elementary schools, held a meeting on Friday last in the rooms of the Society of Arts. Mr. C. J. Addiscott, President of the National Union of Teachers, occupied the chair; and in his opening address he remarked that what is needed at the present time is a sound, workable system of technical instruction, based upon science and art teaching, which itself must be based upon a solid foundation of primary instruction. He discredited the idea that our primary system should be so moulded that it should lead necessarily to a secondary system, believing that the needs of the class with which they had to deal were outside what he conceived to be secondary education, and that the satisfaction of those needs would be found in the development of the primary system through the higher-grade Board school or organised science school on to the technical institute. The main factor for successful progress in this direction must be a central authority, which should be sympathetic, which should know the needs and the difficulties of each class at each stage of the journey. A number of resolutions were passed, one of them being opposed to the recent action of the Science and Art Department in giving instructions to inspectors to report any case where 25 per cent. of the first year students leave the schools at the end of the year, or more than that percentage of the second year students leave at the end of the second year, in order that the department might consider whether such schools should continue to be recognised as schools of science.

The Association of Directors and Organising Secretaries for Technical and Secondary Education met on Friday last at the Guildhall, Westminster. Mr. C. H. Bothamley (Somerset) was elected chairman, Mr. Hewitt (Liverpool) vice-chairman, Mr. J. H. Nicholas (Essex) secretary, and Mr. Turner (Staffordshire) treasurer. The places of the three remaining meetings for 1898 were fixed to take place at Birmingham, Sheffield, and London. In the course of an address, the chairman remarked that the Association had repeatedly expressed its acceptance of the recommendations of the Royal Commission on Secondary Education and had expressed the opinion that they formed a satisfactory basis for legislation. Latterly they had heard a great deal about the essential importance of constituting a central authority for education before anything else was done in the matter. The constitution of an efficient central authority could properly be brought about by the reorganisation of those Government departments that dealt at present with educational matters, a reorganisation along the lines of the Royal Commission's report. They found it to be inconvenient in practice in many ways to have two entirely separate departments, one of which they were brought into contact with in connection with evening continuation schools, and the other more and more frequently in dealing with secondary schools They wanted to see these two departments merged more or less completely into one, with their functions properly defined, and capable of dealing with secondary education as a whole, as well as with the purely scientific and technical part of it. The other part of the central authority—the educational council—was a body to which the scholastic profession naturally attached great importance. The Association thought that one of the great needs of the present time was a system of schools corresponding fairly closely with the higher primary schools of France—schools which should be a real top to the elementary education. He concluded by moving—"This Association considers that legislation on the lines of the report of the Royal Commission on Secondary Education is very urgently needed at the present time." Mr. Turner seconded, and, after a short discussion, the resolution was adopted.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xx. No. 1, January.—"The motion of a solid in infinite liquid under no force," by Prof. Greenhill, examines the elliptic function expression of all the dynamical quantities involved, and explores the analytical field by working out completely the simplest pseudo-elliptical cases to serve as landmarks, utilising the analysis which the author has developed in his paper on "Pseudo-Elliptic Integrals and their dynamical applications," in the *Proceedings* of the London Mathematical Society (vol. xxv.) and carrying out his work on the lines of his papers on the "Dynamics of a Top" and on the "Associated Motion of a Top and of a Body under no Forces" in vols. xxvi. and xxvii. (*Proc. L.M.S.*). Reference is made to the sketch of the theory in Thomson and Tait's "Natural Philosophy," and to a complete solution in the case of a solid of revolution in Kirchhoff's *Vorlesungen über Math. Physik*, ix.; and to the "Motion of a Solid in a Liquid," by Dr. T. Craig.—"Surfaces of Rotation with constant measure of curvature and their representation on the Hyperbolic (Cayley's) Plane," by G. F. Metzler. Minding (Crelle, vols. 19, 20) shows that it is easy to obtain the formulæ which express the relations between the sides and angles of a triangle of which the sides are geodesic lines on a surface of rotation with constant measure of curvature. Mr. Metzler shows that the same method holds for the formula expressing the area of the triangle (*i.e.* in the ordinary spherical formulæ put $a - \sqrt{1}$ *for a, the radius of the sphere*).—"Sur les Méthodes, d'approximations successives dans la théorie des Equations différentielles," par E. Picard, is a note, taken by the editors of the *Journal* from M. Darboux's "Théorie des Surfaces (à la fin du tome iv.).—M. Darboux is the mathematician whose likeness accompanies this number.

Bollettino della Società Sismologica Italiana, vol. iii., 1897, Nos 5, 6.—The microseismographs of the Institute of Physics of the Royal University of Padua, by G. Pacher. A reprint of a paper giving a full account of the Vicentini microseismographs, already noticed in NATURE.—The Latian earthquake of May 8, 1897, by G. Agamennone. A note on a series of slight shocks felt in the neighbourhood of Rome.—The Royal Geodynamic Observatory of Catania, by A. Riccò.—Notices of earthquakes recorded in Italy (April 27–May 14, 1897), by G. Agamennone, the most important being the series of Latian earthquakes of May 8, and an earthquake of distant, but unknown, origin on May 1.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 9, 1897.—"On Methods of making Magnets independent of Changes of Temperature; and some Experiments upon Abnormal or Negative Temperature Coefficients in Magnets." By J. Reginald Ashworth, B.Sc.

The object of this paper was to find what kinds of iron or steel are least liable to changes of magnetic intensity of a cyclic nature under moderate fluctuations of temperature, such as take place in the atmosphere from one season to another. The subject is of importance for the sake of improving magnetic instruments, but apart from its practical consequences the investigation points to some interesting theoretic consequences.

In general the effect of alternately heating and cooling a magnet is to cause a large loss of magnetic intensity, which is only in part recovered; ultimately a cyclic state is established in which the changes may be expressed by a formula which in conformity with custom is here written $I_t' = I_t\,(1 - a\,\overline{t' - t})$, I standing for the magnetic intensity, t and t' for the cold and hot temperatures.

Hitherto a, the temperature coefficient of the magnet, has been found to be positive; that is to say, the effect of a rise of temperature is to diminish, and a fall of temperature to increase the magnetic intensity. A negative coefficient must be understood, therefore, to represent a rise and fall of magnetic intensity with rise and fall of temperature, and this abnormal effect has now for the first time been observed to be general in certain cases.

In the first place the influence of chemical composition was sought in determining the behaviour of a magnet under changes of temperature, and steel alloys severally of manganese, tungsten, cobalt, and nickel were tested, as well as a series of cast irons of different blends of pig irons. The results obtained show that the influence of chemical constituents is subordinate to that of physical condition, annealing or hardening. Thus a kind of nickel steel, the same as Dr. Hopkinson found to yield such remarkable thermo-magnetic results, exhibited in the glass-hard state a small increase of magnetic intensity with increase of temperature and decrease with fall of temperature. When annealed the converse effect took place, and these effects could be changed repeatedly by changing from hard to soft and soft to hard. Again cast iron, in the condition received from the foundry, has a very large magnetic variation for a given range of temperature, but when hardened by heating and rapidly chilling the variation becomes exceedingly small, the coefficient now being about $\frac{1}{15}$th its former amount. As hardened cast-iron magnets have also a very high permanent magnetic intensity, and are very little influenced by shocks and blows, it will be seen that they have exceptionally valuable qualities.

However, the most interesting results were obtained from some steel music wires which happened to be put to the test. These wires in the normal condition and when the cyclic state is established, after experiencing the usual permanent magnetic loss, exhibit a negative coefficient, the higher and lower intensities now corresponding to higher and lower temperatures, and they are thus quite exceptional. But, in contrast with the similar behaviour of the nickel steel alloys just mentioned, the negative coefficient is destroyed and a positive coefficient established if the wire be raised to a bright red heat and cooled either very slowly, as in the process for annealing, or rapidly as for hardening. If heated, however, to about a dull red and quenched, the coefficient can then be rendered just zero.

In order to gain some insight into the cause of this abnormal negative coefficient, the wire was dissolved in nitric acid and at different stages of dissolution tested. This led to the important relation, which was afterwards fully established in every possible way by a series of laborious experiments, that the longer and thinner the wire the more negative is its coefficient; and so much does the coefficient depend on the ratio of length to diameter, or dimension ratio, that by suitably altering the dimension ratio the sign of the coefficient may be changed; and for some particular dimension ratio, for a given kind of steel wire, the coefficient may be made zero, and the magnet is then independent of temperature changes.

The diagram exhibits these changes graphically. Curve (1) represents the variation of the coefficient from positive to negative for steel music wire of diameter 0·187 centimetre, and of lengths 3, 6, 9, 12, 15 and 18 centimetres corresponding to dimension ratios 16, 32, 48, 64, 80 and 96.

Curves (2) and (3) represent similar changes in different steel wires, where the dimension ratio was varied by altering the diameter of the wire and keeping the length constant.

An almost identical curve to No. 1 is obtained by plotting against the dimension ratio the percentage permanent magnetic loss each piece suffers due to the process of alternate heatings and coolings; and as this is, without doubt, dependent on the self-demagnetising force in the magnet, it is evident the co-efficient is also a function of the demagnetising force, and is principally varied by this, at least for a given range of dimension ratios.

The ultimate cause determining the abnormal negative co-efficient in steel music wires of large dimension ratios is not yet completely made out, but experiments now in progress seem to indicate that it is the effect of the drawing in the process of manufacture.

"A Note on some further Determinations of the Dielectric Constants of Organic Bodies and Electrolytes at very Low Temperatures." By Prof. James Dewar, F.R.S., and Prof. J. A. Fleming, F.R.S.

December 16, 1897.—"Memoir on the Integration of Partial Differential Equations of the Second Order in Three Independent Variables, when an Intermediary Integral does not exist in general." By A. R. Forsyth, F.R.S., Sadlerian Professor in the University of Cambridge.

The memoir discusses the theory of partial differential equations of the second order in one dependent and three independent variables; and the method adopted is seen, without difficulty, to be applicable to equations which involve more than three independent variables and which can be of order higher than the second.

In order to solve a given equation, a system of subsidiary equations is constructed; and the system is made up of two parts. One of these parts is a set of simultaneous partial differential equations in two independent variables and a number of dependent variables, this number being one more than the number of the equations. An integral equivalent of this part accordingly contains an undetermined quantity. The other of the parts is a set of equations in a single independent variable; it appears that the set of equations in the second part can be consistently satisfied by a determination of the unknown quantity emerging from the first part.

The first of the three sections, into which the paper is divided, deals with the general theory, and indicates a method whereby subsidiary equations for an equation $F = 0$ of any degree in the derivatives of the second order can be constructed. If integrable combinations of the subsidiary system are not obtainable, an extension of the method shows how equations of higher order (when obtainable) can be deduced and associated with the given equation.

The second of the three sections deals with those equations of which the characteristic invariant is resolvable; and some examples are given, alike of equations for which the integration of the initial subsidiary system is possible, and of equations for which the extended method must be used.

The third of the three sections deals with those equations of which the characteristic invariant is irresolvable. Of such equations the most interesting examples are the potential equation and other equations in mathematical physics; and the theory is applied to some of these equations in detail, leading to some new solutions.

"On the Occlusion of Hydrogen and Oxygen by Palladium." By Ludwig Mond, Ph.D., F.R.S., William Ramsay, Ph.D., F.R.S., and John Shields, D Sc., Ph.D.

Palladium black prepared in the same way as platinum black contains 1·65 per cent. of oxygen, which cannot be removed *in vacuo* at a dull red heat. On heating in an atmosphere of oxygen the amount absorbed up to a red heat was about one and a half times as much as corresponds with the formula Pd_2O, and this also could not be extracted at a dull red heat *in vacuo*.

A comparative study of the occlusion of hydrogen by palladium black, sponge and foil was made; and, after taking into consideration some observations made by Graham and Dewar, it was found that no matter whether the palladium exists as black, sponge, foil, wire, or compact metal, or whether it is charged by direct exposure to hydrogen gas (the proper conditions being observed, as explained), or charged electrolytically, the amount of hydrogen occluded in each case is approximately the same, the atomic ratio palladium : hydrogen varying between 1·37 and 1·47.

The bulk of the hydrogen occluded by palladium black and sponge can be pumped off again at the ordinary temperature *in vacuo*.

The heats evolved per gram of hydrogen and oxygen occluded by palladium black are + 46·4 K (4640 *g*-cal) and + 11·2 K (1120 *g*-cal) respectively, the latter value being in harmony with the view that the absorption of oxygen is a true phenomenon of oxidation.

With respect to the supposed formation of a definite chemical compound on the occlusion of hydrogen, it is shown that Troost and Hautefeuille's deduction that Pd_2H is formed is not warranted. If any hydride is produced at all, it probably contains at least as much hydrogen as that required by the formula Pd_3H_2 first suggested by Dewar.

It is also shown that the heats of occlusion of hydrogen in platinum and palladium black are not in favour of the view which has sometimes been put forward, that the heat of occlusion of a gas represents the heat of condensation or liquefaction of the gas in the capillary pores of the absorbing substance.

Linnean Society, December 16, 1897.—Frank Crisp, Treasurer and Vice-President, in the chair.—Mr. W. Carruthers, F.R.S., exhibited and made remarks upon a fungus, *Rosellinia ligniaria*, which had been found to attack living ash trees, eventually causing the death of the tree. Additional observations were made by Mr. George Murray and Prof. Farmer.—Mr. Edward Step exhibited two specimens of a Hermit Crab, *Eupagurus Prideauxi*, from Portscatho, Cornwall. Both were found naked and in rock-cavities, and special interest attached to the fact that, in the absence of the well-known molluscan shell which the species affects, each specimen was incrusted at precisely the same regions of its exterior by "acorn-shells."—The Rev. T. R. Stebbing gave an account of the habits of this and other species of the genus *Eupagurus*, directing special attention to the work of Aurivillius; and Prof. Howes remarked that it was on record that in the absence of a shell the bowl of a clay-pipe did not come amiss to these animals, and that they will readily utilise broken test-tubes.—Mr. H. M. Bernard read a paper on the affinities of the Madreporarian genus *Alveopora*. The question discussed was one of much interest, owing to the claim advanced by Dana, that *Alveopora* is a survival of the great Palæozoic family *Favositidæ*. This claim was rejected by

Milne-Edwards and Haime, but nevertheless was founded on close similarity of structure. Other important characters in common were now indicated, viz. the similarity of the earliest growth-stages and of the method of budding. These were described, and it was urged that there was now no reason to doubt the relationship between *Alveopora* and *Favosites* other than that which arose from the immense interval of time which had elapsed since *Favosites* flourished and from the scarcity of intermediate forms. One only had been described, viz. the genus *Koninckia* from the Cretaceous. Mr. Bernard then discussed the relationship of *Alveopora* with the recent *Poritidæ*, in which family it is usually classed. The author contended that *Alveopora* and *Poritidæ* stand about as far apart as possible in the madreporarian system, and with regard to the evolutionary stages of the madreporarian skeleton he concluded that the original columniform polyp must be considered to have had the lower portion of its body clothed with a stiff secretion which formed a cup into which the upper flexible portion could be invaginated This epithecal cup was the primitive madreporarian skeleton. Within this cup—mainly by infoldings, at first simple, but soon increasing in complexity—a new internal skeleton had been developed which had largely superseded the primitive epithecal skeleton. This internal skeleton, he thought, was as much a product of the epitheca as the apodematous systems of Arthropods are products of the chitinous cuticle. A discussion followed, in which the Chairman and others took part.—Messrs. H. and J. Groves communicated a paper on some *Characeæ* collected by Mr. T. B. Blow in the West Indies, one of which appeared to be new to science. Specimens of the plants described were exhibited.

PARIS.

Academy of Sciences, January 3.—M. A. Wolf in the chair.—M. Van Tieghem was elected Vice-President for the year 1898.—M. Chatin, the outgoing President, announced the changes in the Members and Correspondents during the year 1897.—General method for determining fundamental stars and latitude, by M. Lœwy. A further developement of the method announced at the previous meeting.—Histogenetic influence of an anterior form, with respect to the regeneration of Descemet's membrane, by M. L. Ranvier. It is known that the introduction of a single crystal into a solution has a considerable effect in causing crystallisation, and the present observations tend to show that an analogous phenomenon may take place in organic tissues. Observations were made upon the growth of the membrane of Descemet and its endothelium in the cornea of a rabbit, after partial destruction by incision and by a needle. In the latter case, where the corneal layers attacked by the needle have given an irregular surface, the endothelium, instead of forming a simple cellular layer, appears in the form of small masses, in which several layers of cells can be seen. The definition of endothelium thus requires considerable modification.—On the determination of the first terms of flexure of a meridian instrument. Application to the meridian circle at the Observatory of Paris, by MM. W. Ebert and J. Perchot.—On the conformable representation of one surface upon another, by M. G. Souslow.—On the velocity of propagation of a movement in a medium at rest, by M. P. Vieille. A description of experiments upon the velocity of the wave produced by exploding varying charges of powder and fulminating mercury in a steel tube. The figures obtained show that as the initial condensations increase, the mean velocities of propagation on a length of four metres also increase from values about the velocity of sound up to four times that speed.—On a new method of interferential spectroscopy, by MM. A. Perot and Ch. Fabry. The interferential spectroscope is composed of two plates of plane glass with silvered faces opposed, the distance and orientation of which can be exactly regulated. The rings produced are observed at an infinite distance, the system being lighted by a slightly converging bundle of rays. With this apparatus M. Michelson's statement that the green ray of thallium is double has been verified.—On the mechanism of the discharge of conductors struck by the X-rays, by M. G. Sagnac. The surface of a metal, M, struck by the X-rays emits new rays termed secondary rays of the metal M. Each element of volume of gas adjacent to the metallic conductor is rendered capable of conducting electricity, both by the incident X-rays and by the secondary rays.—On a simple method for directly transforming typographical plates and other objects in feeble relief into photographs, by M. Adrien Guébhard.—On the isocyanic ethers and the heat of formation of liquid isocyanic acid, by M. Paul Lemoult. The heats of formation were determined of the isocyanates of methyl and ethyl by the method of the calorimetric bomb.—On a new cyclic ketone methylcylohexonone, by M. A. Béhal. This ketone is one of those obtained from wood oil. Oxidation with potassium permanganate gave only acetic and levulic acids. The benzoyl derivative and oxime were prepared. —Preliminary note on the origin of the subrenal capsules of lophobranchial fishes, by M. Huot. The subrenal capsules have been usually regarded as arising from the epithelium of the cœlom, but the study of the development of these organs in the embryos of *Syngnatus Dumerilii*, leads to the conclusion that they arise from two sunk diverticula each of which is a bud from the posterior portion of a Wolf's canal.—On the origin of the setigerous bulbs and the nephridia in Annelids, by M. Aug. Michel. In the caudal regeneration of the Annelids, the setigerous bulbs are ectodermic and the setigerous sacs are mesodermic; the nephridia are of a neutral origin, ectomesodermic.

AMSTERDAM.

Royal Academy of Sciences, November 27, 1897.—Prof. van de Sande Bakhuyzen in the chair.—Prof. van der Waals gave an approximate rule for the course of the plaitpoint-curve of a mixture. The curve constructed according to the rule given will correspond very closely with the actual plaitpoint-curve in the case of all those mixtures, which present the circumstance that a maximum or a minimum tension occurs, if the components have a certain ratio to each other, as is the case with mixtures of N_2O and C_2H_6. The curve for the said mixtures, according to Kuenen's observations, is explained in all its details by this rule.—Prof. Moll on an inquiry by Mr. Van Wisselingh into the nucleolus of *Spirogyra*. The principal results of this inquiry are: (1) besides the usual form of karyokenesis *Spirogyra crassa*, Kütz, has also a second form, in which no nuclear segments are produced; (2) in the division with segmentation ten out of the twelve segments originate in the nucleus itself, while two originate in the nucleolus; (3) in the case of nuclear division with segmentation the nucleolar segments have each a resistant thread, by which they are distinguished from the rest. The resistant threads divide longitudinally, like the segments themselves, and the two halves contribute in the daughter nucleus towards the formation of the new nucleolus. In the case of nuclear division without segmentation the nucleolus also produces two resistant threads, which in the division behave in exactly the same way as in karyokenesis with segmentation.—Mr. Eykman on the influence of the seasons on combustion of nutritive matter in man. The speaker communicated the results of a comparative inquiry into the respiratory exchange of gases in winter and in summer. With the nine persons, upon whom he experimented, the speaker found the average consumption of oxygen, when they were in a state of bodily rest, to be no smaller in summer than in winter, and concludes, also, on the ground of previous investigations made by him in India, that in man there exists no appreciable chemical regulation of heat.—Prof. V. A. Julius presented on behalf of Mr. N. G. van Huffel a short paper on magnetic hysteresis in a long soft iron bar. Round the middle of the bar was a primary coil; a secondary coil could be placed at various distances from the primary one. At a certain moment, varying from 1/3 to 2 seconds after the primary circuit was closed, the secondary one was for $\frac{1}{100}$ second brought in contact with a ballistic galvanometer. It appeared that the rate of change of induction reached a maximum at a certain distance from the middle of the bar, and that the maximum displaced itself with the increase of the time from the middle towards the ends of the bar.—Prof. van Bemmelen communicated on behalf of Mr. Schreinemakers the results of an inquiry into the equilibrium in systems of three components, in which two and three liquid phases occur.—Prof Kamerlingh Onnes presented on behalf of Dr. W. van Bemmelen a paper, entitled "a provisional notice of new acquisitions of older observations of magnetic variation, among others by Parmentier in 1529, Cavendish in 1587, and by French navigators in the Pacific about the year 1700."—Prof. van der Waals presented (*a*) on behalf of Prof. Dibbits a paper by Dr. A. Smits, on an instrument for keeping the tension above a boiling liquid constant. The space in which the space is to be kept constant, is connected with a U-shaped barometer. When the pressure decreases, the mercury rises in the shorter limb and, in consequence of this, a galvanic circuit is closed, through which a blowing-apparatus is put in action; when the pressure increases, a sucking-apparatus is put in action by another galvanic circuit. When the oscillations of the mercury are small, the tension can be kept constant within very narrow limits. (*b*) On behalf of Prof. W. Kapteyn a paper on certain definite integrals. According to Cauchy the sum of the residues of a function which is meromorphic within a certain space, may be represented by an integral along the circumference of the space as well as by the sum of the coefficients of the first negative powers of the coefficients of this function in the proximity of the poles. The author applies this principle to a function consisting of the product of $l\left(\frac{1-s}{1+s}\right)$, with a function, which is meromorphic within the circumference of a circle described out of the origin with the unit for radius.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 13.

MATHEMATICAL SOCIETY, at 8.—Note on a Property of Pfaffians: H. F. Baker.—On the Stationary Motion of a System of Equal Elastic Spheres of Finite Diameter (continuation): S. H. Burbury, F.R.S.—On Discontinuous Fluid Motion: B. Hopkinson.—On the Intersections of Two Conics of a given Type, and on the Intersections of Two Cubics: H. M. Taylor.—On the Continuous Group defined by any given Group of Finite Order: Prof. W. Burnside, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Presentation of Premiums.—Inaugural Address of the President, Joseph W. Swan, F.R.S.

FRIDAY, JANUARY 14.

ROYAL ASTRONOMICAL SOCIETY, at 8.—The Ternary System Lac. 7215 = *h* 4935: R. T. A. Innes.—The Double Star ζ Boötis = Σ 1865: S. W. Burnham.—The Orbit of OΣ 400: S. W. Burnham.—Note on the Result concerning Diffraction Phenomena recently criticised by Mr. Newall: F. L. O. Wadsworth.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Mechanical Draught: R. Gordon Mackay.

MALACOLOGICAL SOCIETY, at 8.—Note on the Reno-pericardial Pore of *Ampullaria urceus*: R. H. Burne.—On some Points in the Anatomy of *Sepia officinalis*: R. H. Burne.—On an Example of *Acanthoteuthis Férussacii* from the Lithographic Stone of Solenhofen, Bavaria, exhibiting the Buccal Membrane: G. C. Crick.—Descriptions of Four New Species of Land Shells from New Guinea, North Borneo, and Aldabra Island: E. A. Smith.—On the New Land Shells of the Island of Lombock: E. A. Smith.—Description of Two New Species of *Clausilia* from Che-kiang Province, China: Mrs. Kenyon.

MONDAY, JANUARY 17.

SOCIETY OF ARTS, at 4.30.—My Recent Journey from the Nile to Souakim: Frederic Villiers.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Journeys in the East Coast Provinces of Siam: H. Warington Smyth.

VICTORIA INSTITUTE, at 4.30.—The Glacial Epoch: Prof. E. Hull, F.R.S.

TUESDAY, JANUARY 18.

ROYAL INSTITUTION, at 3.—The Simplest Living Things: Prof. E. Ray Lankester, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Paper to be further discussed: The Machinery used in the Manufacture of Cordite: E. W. Anderson.

ZOOLOGICAL SOCIETY, at 8.30.—On the Vascular System of the Chiroptera: Dr. N. H. Alcock.—On the General Anatomy of the *Holocephali*: L. W. Byrne.—On the Development of the Hyobranchial Skeleton of the Midwife-Toad (*Alytes obstetricans*): Dr. W. G. Ridewood.

ROYAL STATISTICAL SOCIETY, at 5.30

ROYAL VICTORIA HALL, at 8.30.—Through the New Gold Fields of Alaska to Bering Strait.

WEDNESDAY, JANUARY 19.

SOCIETY OF ARTS at 8.—The Projection of Luminous Objects in Space: Eric Stuart Bruce.

GEOLOGICAL SOCIETY, at 8.—On some Gravels of the Bagshot District: H. W. Monckton.—On the Occurrence of Chloritoid in Kincardineshire: George Barrow.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Ordinary Meeting.—At 7.45.—Annual General Meeting.—Address by the President (E. Mawley) on Weather Influences on Farm and Garden Crops.

ROYAL MICROSCOPICAL SOCIETY, at 8.—President will read his Annual Address.

ENTOMOLOGICAL SOCIETY, at 8.—Annual Meeting.—Address by the President, R. Trimen, F.R.S.

INSTITUTION OF MINING AND METALLURGY, at 8.—Notes on the Action of Cyanogen on Gold: James Park.—Mexican Methods of Mining: S. B. Newall.—On the Successful Treatment of Tailings by the Direct Filling Process on the Witwatersrand: F. Cardell Pengilly.

THURSDAY, JANUARY 20.

ROYAL SOCIETY, at 4.30.—The Relations between Marine Animal and Vegetable Life: H. M. Vernon.—(1) The Homogeneity of Helium; (2) Fergusonite, an Endothermic Mineral: Prof. W. Ramsay, F.R.S., and Morris W. Travers.—On the Modifications of the Spectra of Iron and other Substances radiating in a Strong Magnetic Field: T. Preston.

ROYAL INSTITUTION, at 3.—The Halogen Group of Elements: Prof. Dewar, F.R.S.

SOCIETY OF ARTS, at 4.30.—Recreations of an Indian Official: Right Hon. Sir Mountstuart Elphinstone Grant Duff, G.C.S.I., C.I.E., F.R.S.

LINNEAN SOCIETY, at 8.—On the Larval Hyobranchial Skeleton of the Anurous Batrachians, with special reference to the Axial Parts: Dr. W. G. Ridewood.—On the "Abdominal Pore" in the Myxinidæ: R. H. Burne.

CHEMICAL SOCIETY at 8.—Ballot for the Election of Foreign Members.—The Action of Caustic Alkalies on Amides: Dr. Julius B. Cohen and Edward Brittain.—The Formation of Monomethylaniline from Dimethylaniline: Dr. Julius B. Cohen and H. T. Calvert.—Note on the Aluminium-Mercury Couple: Dr. Julius B. Cohen and H. T. Calvert.—Action of Chloroform and Alkaline Hydroxides on the Nitro-benzoic Acids: W. J. Elliott.—Researches on the Terpenes. II. On the Oxidation of Fenchene: J. Addyman Gardner and G. B. Cockburn.—The Preparation of Pure Iodine: Dr. Bevan Lean and W. H. Whatmough.

FRIDAY, JANUARY 21.

ROYAL INSTITUTION, at 9.—Buds and Stipules: Sir John Lubbock, Bart., M.P.

PHYSICAL SOCIETY, at 5.—On Electric Signalling without Conducting Wires: Prof. O. Lodge, F.R.S.—A Tesla Oscillator will be exhibited by Prof. S. P. Thompson, F.R.S.

BOOKS AND SERIALS RECEIVED.

BOOKS.—Practical Ethics: Prof. H. Sidgwick (Sonnenschein).—Ordinary Differential Equations: Dr. J. M. Page (Macmillan).—Euclid's Elements of Geometry, Books 1 and 2: C. Smith and Dr. S. Bryant (Macmillan).—Practical Toxicology for Physicians and Students: Dr. P. Kobert, translated and edited by Dr. L. H. Friedburg (New York, Jenkins).—Psalms of the West, 3rd edition (Longmans).—The Tears of the Heliades, or Amber as a Gem: W. A. Buffum, 3rd edition (Low).—A Trip to Venus: J. Munro (Jarrold).—Tabellarische Übersicht der Mineralien: P. Groth, Vierte Vollständig neu Bearbeitete Auflage (Braunschweig, Vieweg).—Third Annual General Report upon the Mineral Industry of the United Kingdom, 1896: Dr. C. le Neve Foster (Eyre).—A Treatise on Chemistry; Roscoe and Shorlemmer. Vol. 2. The Metals, new edition (Macmillan).—Geometry for Beginners: Prof. Minchin (Oxford, Clarendon Press).—From Tonkin to India; Prince Henri d'Orléans, translated (Methuen).—Seventeenth Annual Report of the U.S. Geological Survey, Parts 1 and 2 (Washington).—University College, Sheffield, Calendar for the Session 1897–98 (Sheffield).—The Cyclist's Pocket-Book (Constable).—General Report on the Operations of the Survey of India Department, 1895–96 (Calcutta).

SERIALS.—Scribner's Magazine, January (Low).—Among British Birds in their Nesting Haunts: O. A. J. Lee, Part 8 (Edinburgh, Douglas).—Geographical Journal, January (Stanford).—Observatory, January (Taylor).—Records of the Australian Museum, Vol. iii. No. 3 (Sydney).—The Atoll of Funafuti, Part 5 (Sydney).—Brain, Part 79 (Macmillan).—An Illustrated Manual of British Birds, new edition, January (Gurney).—Bulletin from the Laboratory of Natural History of the State University of Iowa, December (Iowa).—Mind, January (Williams).—Bulletin of the American Mathematical Society, December (New York, Macmillan).—Revue de l'Université de Bruxelles, January-February (Bruxelles).—Knowledge, January (High Holborn).—Records of the Geological Survey of India, Vol. xxx. Part 4 (Calcutta).—Atlantic Monthly, January (Gay).—History of Mankind: F. Ratzel, translated, Part 23 (Macmillan).—Notes from the Leyden Museum, July and October (Leiden, Brill).—Journal of the Asiatic Society of Bengal, Vol. lxvi. THE PHYSIC OF OUR FATHERS.

Vita Medica; Chapters of Medical Life and Work. By Sir Benjamin Ward Richardson, M.D., LL.D., F.R.S. Pp. xvi + 496. (London: Longmans and Co, 1897.)

THIS work, Mr. Bertram Richardson tells us, was finished by his father on Wednesday, November 18, 1896, just before eight o'clock in the evening. At ten he was seized with the illness which ended fatally on Saturday morning, November 21. Thus a pathetic interest attaches to these last words of a singularly interesting and gifted man. Not a few errors in the text, such as the misspelling of proper names, and so forth, are due no doubt to the want of the author's revision.

The work may be roughly divided into the biographical part, and a second part in which the author, as if with a prescience of death, tells us of the ideas which had occupied his thoughts in his later years. We trust that we may be forgiven for saying that the former part is by far the more interesting. If Sir Benjamin's style occasionally offend the purist, he nevertheless writes in a vigorous, graphic, and even picturesque fashion, which is far better than mere purity. Although no one would have been more reluctant than the author himself to have his style compared to that of so splendid and accomplished a master of prose as Mr. Ruskin, yet we admit that on reading the first part of this book we were reminded of the charming "Praeterita," in its winning egotism without self-conceit, its happy delineation of character, and its broad humanity. We were greedy of more, and confess to a disappointment when other matters, which the author no doubt regarded as more important, cut short the personal narrative. Not only so, but the narrative itself is diversified by reflections always shrewd and kindly, often acute and original. The admirable portraits of those most interesting of men the old-fashioned country practitioners of medicine—such as Dudley Hudson and Willis—are excellent; in these pages the abler sort of country doctor, with his rugged kindliness, his curious stores of ill-digested learning, his flashes of humorous insight, his devotion to his calling, and his readiness of resource in emergencies, is described to the life. The modern practitioner, however, has some grasp of principles, whereas his predecessor, for the most part, hated ideas; if the modern doctor be inferior to his predecessor in mother wit, less curious in his mental furniture, and wanting in the vigorous eccentricity of manner and thought which made his predecessor entertaining as a character, yet his education in scientific methods makes him a far more enlightened practitioner of a very abstruse and complicated art. We insist on this distinction between the scientific physician and the merely practical doctor, because we think Sir Benjamin Richardson, in his advocacy of the old system of apprenticeship, which no doubt taught well the arts of managing men and horses and of smelling out drugs in the dark of the night, left out of view that cultivation in the broader principles of medicine as a science which nowadays mark the modern practitioner even in country [illegible]. For lack of a greater breadth of mental training the Dudley Hudsons, the Willises, and the rest, keenly as they loved curious detail, gained no wide reputation. Moreover, but few apprentices had remarkable men for their teachers; "first catch your despot." The men who stimulated and instructed the young Richardson were singularly able men; too many medical apprentices fell under the guidance of masters whose endowments, natural or acquired, were often little above those of the contemporary cow doctor.

Many points of more than local interest are touched upon in the course of the biographical sketch. Richardson emphasises the part taken by Perry of Glasgow in making known in Great Britain the distinction between enteric and typhoid fevers. Dr. A. P. Stewart, a pupil of Perry, helped to make popular the distinction so clearly taught by his master. The author also gives a very graphic account of the first operation under anæsthetics in Glasgow, by Andrew Buchanan.

Of that remarkable little town Saffron Walden, with its museum and its group of clever men, a very interesting account is given. The Exhibition of 1851 is recalled; and Richardson tells us that its effect—and we may add that of the development of the railways—on the health of women, and consequently on the doctor's income, was one of its unexpected results: women whose lives had been spent in valetudinarianism rose from their sofas, and in the second half of the century forgot that the daily or weekly visits of the doctor had for generations been the principal event in the lives of themselves and such as they. To cycling as a means of health the author gives the same credit. Among other interesting facts he tells us also that he frequently attended in the camps of the gypsies, and found that this nomad way of life was far from a healthy one for the children of these folk. In this and innumerable other departments of his life's work the author cannot prevent our perceiving that his devotion to the sick and sorrowful was at least as exemplary as that of those others of the noble band of general practitioners to whose ranks he then belonged, and whose self-denying labours he has so admirably recorded.

Even in the scientific investigations, which more and more occupied his maturer life, love of man and an earnest desire to benefit his race were prominent. Fruitful as such aspirations are, Richardson might perhaps have done more for science if this love of knowledge had been more disinterested. We must not forget that even Pasteur's work was chiefly inspired by the hope of discovering the means of benefiting his fellow men, yet Richardson was not perhaps wholly free from some tinge of that Philistinism which too often colours the ideas of the benevolent man.

Perhaps Richardson's best work was that on the anæsthetic agents, and on the methods of anæsthesia, whether general or local. In the same spirit he sought a remedy for the terrible effects of clotting of the blood in the heart, or blood-vessels; and certainly the cases quoted by him in support of the method he advised, must command attention. In the sphere of antiseptic surgery, also, he worked hard at a time when its principles were so little understood that the author himself, neither then nor afterwards, was able to lay hold of the principles of bacteriology, on which study he makes adverse and belated reflections. We were unaware that while working at the ethers Richardson had recommended nitrite of amyl in angina pectoris, a therapeutic discovery which has been attributed to others.

The enthusiasm for humanity which dictated so many of these researches, led Richardson to the front of the battle in the causes of preventive medicine and of teetotalism. His splendid services in the field of sanitary reform are too well known to need record in these columns; his determined advocacy of total abstinence, no doubt, as he tells us, to his own pecuniary detriment, sprang again from his ardent humanity. Whether, right or wrong, he was as a lion in his aweless championship of all measures which, in his opinion concerned the well-being of the masses. At the same time, his report of the social ignominy which overtook those who advocated this unpopular cause, seems to us exaggerated. Higginbottom, of Nottingham, may, of course, have strode down the room at the Provincial Medical Association unregarded and even shunned of men; but the present writer well remembers the honour in which Higginbottom was held by his contemporaries in spite of his determined opposition to the use of alcohol; and the writer, who also enjoyed the friendship of other prominent teetotallers, such as Edward Baines, never heard worse words spoken against these blameless men than that they were the victims of a troublesome whim. In practice the public not unnaturally fight shy of a faddist, as they supposed the teetotaller to be; but, except in the society of topers, surely no teetotaller as such was ever shunned. Sir Benjamin's nephelococcygian dream of the ideal City of Health made a great effect upon the audience to whom the address was given. The earnest purpose and the fervent desire of the orator to benefit mankind gave a reality to a scheme which, of course, he put forward more or less as a phantasy.

In dwelling on the life of Sir Benjamin Richardson we are led to wonder how it was that a man so earnest, so able, so fertile in speculation, so ardent in his laboratory researches should have achieved comparatively little of permanent scientific value. On the other hand, we shall not forget that much of his energy was given to inspiring and directing the men of his time in social work which, if it cannot be formulated, was none the less permanent in its effects. We have hinted that the speculative part of the volume before us is less interesting than the narrative: the thoughts are turned out upon paper in a crude state, and, generally speaking, are no more than the floating thoughts of any able and thoughtful man. Nay, we cannot but feel that in their form we observe the ill effects of the very apprenticeship that he believed to be the best early education for a medical man. We believe that a more systematic training in scientific method in his earlier days would have led not only to a chastening of such speculations, but also to the attainment of scientific discoveries of a more abiding value. Nevertheless, we put down this book with a sense that men of Richardson's stamp—courageous and unwearied in the pursuit of truth—are the salt of our race; and that even in the most unsubstantial of his musings there is always an elevation of tone which reveals the noble and humane character of one so long a familiar figure among us, but whose voice we shall hear no more.

T. C. A.

A NEW WORK ON POPULAR ASTRONOMY.

The Concise Knowledge Astronomy. By Agnes M. Clerke, A. Fowler, A.R.C.S., F.R.A.S., Demonstrator to the Royal College of Science; and J. Ellard Gore, F.R.A.S., M.R.I.A. With illustrations from photographs and drawings. Pp. x + 581. (London: Hutchinson and Co., 1898.)

THIS is a formidable array of authors, and the necessity for such a numerous combination is not at all clear. There is nothing in the book that any one of the three could not have written, and we might add that any one of the three could have written a better book, than the united efforts of the three have produced. While the separate parts, judged from a popular standpoint, are in many respects admirable, there is a want of cohesion in the whole, that is disappointing and unsatisfactory. Collaboration to be effective must be close and thorough; but here, facts are repeated by the separate authors in a way which annoys, and statements are divided between the different writers in a manner which disturbs, a reader. Efficient editing could have prevented a good deal of this overlapping, and have dovetailed the parts together with more skill; but the cumbrous machinery that necessitated an editor at all was a mistake. Can any one suppose that there is any material gain in taking the chapters on the sidereal universe out of Miss Clerke's hands and placing them in those of Mr. Gore, or that Mr. Fowler was incapable of describing the main features of the several members of the solar system? Judging from the result before us, an elementary book is not increased in accuracy nor benefited in arrangement by distributing the compilation among several authors.

Of the trinity here under consideration, Miss Clerke is the largest contributor. To her is entrusted the opening chapters, sketching the history of the science from Hipparchus to the present time. In her hands, a sketch, however brief, is sure to be well arranged and graphically written. We confess, however, to a little disappointment that more space is not given to the development of spectroscopy, and this remark applies not only here but throughout the book generally. Owing to considerations of space it might have been necessary to curtail, or even to exclude, all reference to Mohammedan, and possibly to pre-Newtonian science in these opening chapters; but this loss would have been more than compensated by impressing on the average reader the importance of astrophysics and the part it plays, and in the immediate future, will play, in the development of astronomical science. It must be, no doubt, always a difficult task to know what facts are to be suppressed, and to what others prominence must be given, in order to preserve in due perspective the salient features that mark the onward progress of a science. But full advantage has not been taken of the marvellously rapid development of astrophysics to make it an incentive to the study of astronomy. The facts, and possibly the speculations, of spectroscopy have a great fascination for the general reader. The results can be presented without reference to mathematical formulæ, and by the powerful appeal they make to the imagination, they are eminently calculated to excite public enthusiasm and arouse an intelligent interest in the community. Surely one of the objects, if not the main object of such a book as this, is to promote the cultivation of the science among an instructed, but not specially instructed, public. For whom else is the book written? It is not a work of reference intended to be used by the astronomer; it is not sufficiently full. The earnest student of astronomy is catered for by treatises of a more serious character. In point of fact the book occupies, to some extent, the ground which Sir Robert Ball has so well covered, and appeals generally to the same class of readers.

Another disadvantage springs from this slight, and Miss Clerke must pardon us if we say, unworthy, sketch of spectroscopic advance. Justice is not accorded to those who have worked strenuously and successfully as pioneers in this branch of science. One unacquainted with the history of the science might suppose that our knowledge of it began and ended with the work of Sir William Huggins. We do not mean to imply that there is one word here that is not justified by his great reputation, but only to regret that the names of other equally earnest and equally capable workers are suppressed. We think the omission of all reference to the work of other physicists, both at home and abroad, makes the survey of the general progress of the science too incomplete, and might indeed be likened to the representation of Hamlet with the omission of the Prince of Denmark. No doubt the prominence given to some astronomers, and the silence maintained with regard to others, are accidental; but it unfortunately suggests that the author's mind is warped in special directions, preventing a wholly unprejudiced survey being taken, and suggesting a biassed arrangement of the facts. Happily, in such an elementary work, when we come to greater detail, points still open to controversy and further elucidation do not come before us. We have only to deal with admitted and recognised truths, and here Miss Clerke is a safe guide. The section describing the solar system leaves little to be desired; few could probably have arranged an equal number of facts in the same space without becoming dull and wearisome. By the admirable illustrations supplied, we are in some instances enabled to see the planets and the details of their surface markings as they are revealed in the most powerful telescopes, while the latest views and speculations of the observers are recorded with ample fulness. We anticipate that on this section the general reader will dwell with the greatest interest and delight.

Mr. Fowler's work, without much reason, is sandwiched in between the preliminary historical chapter and this description of the solar system. It is termed geometrical astronomy, not a very happy title, but spherical was, no doubt, felt to be too ambitious a description, and it certainly does deal with many of the problems that belong to the earth's figure and motions. Trigonometrical expressions are practically excluded, but by the aid of diagrams a good many simple problems are very satisfactorily explained. The description of instruments is an interesting feature in this section, and is written with that simplicity and clearness which characterises all Mr. Fowler's work when dealing with mechanical operations.

Mr. Gore furnishes the last part of this trilogy. His domain is the sidereal heavens, and, considering the space at his disposal, his work is very thoroughly done. We could have wished, and so possibly did Mr. Gore, that he had been allowed to use Greek letters to designate the stars in their respective constellations. An uncomfortable strange appearance is given to many old friends dressed up in this unfamiliar fashion. But when one gets over this peculiarity it will be found that the facts connected with binary systems, with temporary and variable stars, with the motion of the sun are clearly and accurately stated, and give a very complete idea of the present condition of our knowledge of the sidereal heavens.

A few very obvious errors are occasionally met with in the course of the book; but where so much has been read with pleasure, it seems a very ungracious task to place the finger on these few blots, which, no doubt, will disappear in subsequent editions. If any one prides himself on his accuracy, let him write an elementary textbook on a subject in which the facts are continually accumulating, and the deductions from them being constantly modified, and he will probably find that his self-complacency is scarcely warranted.

W. E. P.

OUR BOOK SHELF.

Manuel d'analyse chimique appliquée a l'examen des produits industriels et commerciaux. By Émile Fleurent. Pp. iii + 582. (Paris: G. Carré et C. Naud, 1898.)

The author states in his preface that he has written with a threefold aim, namely: (1) to give general methods of qualitative and quantitative mineral analysis and organic analysis of an elementary character, free from all details not absolutely useful; (2) to avoid methods of work that are too long for those who are pressed for time or who have not sufficient general knowledge, giving in each case only one method (or occasionally two) that leads quickly and surely to the desired result; and (3) to bring together in one volume the methods of examination of *the more important*, though the most diverse of the products which one meets with in the laboratory of the industrial chemist. Accordingly we find in some 556 pages of clearly printed and well-spaced matter some preliminary observations with reference to apparatus, a section on qualitative analysis, and methods for the quantitative examination of the commoner metals and minerals containing them, besides, among other things, water, inorganic pigments, cements, &c., compounds of the alkalis, manures of various kinds, soils, animal and vegetable products, such as cellulose, tannin, milk, fruits, fermented liquors, wines, and textile fabrics, the estimation of acetone in methylated spirit, and the determination of the flashing point of petroleum, &c. *It is obvious that* where so much ground is covered in so comparatively small a space, that in some cases at least there cannot be room for more than a mere summary of the details of the method given. It is generally a matter of opinion as to which is the best of several alternative methods, and often, too, a slight variation in the sample from what is most usual, renders a variation in the process desirable. It must have been a very difficult task to select the one or two methods in each case; but, taken as a whole, they are fairly representative. If the space devoted to the figures of beakers and other apparatus, and to the exceedingly meagre description of the qualitative reactions of the common acids and bases had been devoted to an expansion of the other part of the book, the usefulness of the volume would have been much increased. We doubt, for example, the need for telling any one who concerns himself with such work as is here described, that mercuric salts give a precipitate with sulphuretted hydrogen which changes from white to black, and is insoluble in alkaline sulphides; that hydrochloric acid and chlorides give no precipitate, and that iodide of potassium gives a beautiful red precipitate very soluble in excess of the reagent. These are all the qualitative reactions given for mercuric salts, and it may well be said of them that, though true, they are not the whole truth even concerning the precipitates mentioned. As a reminder for students who have to learn what they can about many things in a very little time, the volume will no doubt prove very valuable, and the practical analyst will sometimes find suggestions that will prove useful to him.

First Book of Physical Geography. By Ralph S. Tarr, B.S., F.G.S.A. Pp. xxviii + 368. (New York: The Macmillan Company. London: Macmillan and Co., Ltd., 1897.)

PROF. TARR explains that his reasons for following his "Elementary Physical Geography" (noticed in NATURE, vol. liii. p. 293) by the present smaller work, is that "many teachers who wish to give instruction in the *new physical geography* are unable to make use of it," on account, apparently, of the educational regulations in the United States. Although Prof. Tarr italicises the *new physical geography*, we are unable to see that this book differs essentially in subject-matter from such a long established schoolbook as Geikie's "Elementary Lessons in Physical Geography"; and although with regard to arrangement and style there are variations, these present no special novelty.

Part i. deals with the earth as a whole, and some facts of astronomy; Part ii.—entitled "The Atmosphere"—also touches on light, heat, electricity, magnetism, and the distribution of animals; Part iii. treats of the ocean; and Part iv. of the land. The last part is by far the best from every point of view, and the treatment of the action of rivers on the land is quite beyond anything we have seen in other books of similar scope. This department of physical geography has received more attention in America than in Europe, and we are grateful to Prof. Tarr for the way he has handled it. It is unfortunate that the other parts do not rise to the same level. The illustrations, however, are all very good.

No doubt some terms are used in a different sense in this country and in America, *e.g.* physiography, which here is wider than physical geography, is there restricted to geomorphology. It appears that *zone* is held to signify simply a division, *e.g.* "there are three great zones of life . . . the ocean, the land, and the fresh water" (p. 165); and "in lieu of" (p. 27) is used where we would say "in view of." The term adulteration, on p. 33 ("nitrogen . . . acts as an adulterant to the active oxygen in a manner similar to the adulteration or weakening of a solution of salt when water is added to it"), is used evidently in the sense of dilution, and is not intended to convey any suggestion of fraudulent mixture. But, making allowance for differences of custom in the use of words, we have noted several cases of very slack or even careless definition. There is also a want of attention to the minutiæ of terminology which must be very puzzling to the teachers who use this book, if their mode of doing so is the same as that adopted by their brethren in this country. In a new edition these blemishes will doubtless disappear, and we point them out merely with that object. Such vague sentences as the following, on wind as the cause of waves, should also be revised: "If the wind continues, and especially if it freshens, the waves become higher, for the cause is increased because then there is more friction" (p. 206).

The occasional descriptions of instruments, *e.g.* the psychrometer, anemometer, and especially the deep-sea sounding-rod, are inadequate and sometimes misleading. On the current chart (p. 214) the important and very distinct Agulhas current is not named; and in the sketch-map of the distribution of volcanoes, on p. 355, the active volcanoes which have been definitely proved to exist in Central Asia and Central Africa are not shown.

H. R. M.

Arii e Italici. By G. Sergi. Pp. iv + 228. (Torino: Fratelli Bocca, 1898.)

PROF. SERGI may be congratulated on the lucid manner in which he describes the earliest inhabitants of Italy, and the effects produced by the various invasions of that country. From conclusions drawn from anthropological observations he leads us to believe that the Aryans first invaded Italy from the north-west, and established themselves on the banks of the river Po, terramara being found in that locality. These mixed with the Mediterranean race, and spread south-east, leaving the country around Genoa undisturbed; towards the end of the eighth century before the Christian era, the Etruscans landed on the banks of the Tiber and mixed with the inhabitants of Umbria. No satisfactory explanation of the foundation of Rome is offered.

Anthropological detail is restricted to skulls found in tombs; the method of description is that first introduced by the author, which is based upon the appearance of the skull viewed in *norma verticalis*.

The construction of terramara and lake dwellings, the various kinds of pottery and vases, are briefly described in the chapters dealing with archæology.

The origin of the Italian language and the anthropological evidence in favour of the suggestions of Schleicher, Lottner, &c., is carefully weighed.

It would assist the study of ethnology if the inhabitants of the other European countries were dealt with in as brief and scientific a manner as those of Italy have been by Sergi in "Arii e Italici."

Laboratory Practice for Beginners in Botany. By William A. Setchell, Ph.D., Professor of Botany in the University of California. Pp. xiv + 199. (New York: The Macmillan Co. London: Macmillan and Co., Ltd., 1897.)

THIS little book is, on the whole, admirably calculated to fulfil the intentions of its author. The young student is directed to observe simple and readily accessible objects, and his reasoning faculties are at the same time stimulated by an indication of the general principles which the selected examples are intended to illustrate. By the time he has worked through the book, a boy will have acquired a fair knowledge of the gross structure of plants—a knowledge quite as important as that of minute structure which he too often has never seen for himself, or of physiology which, when ignorant of chemistry and physics, he cannot understand.

Some of the suggestions to the teacher are excellent, but we can hardly praise the selection of literature suggested for his use. A teacher ought to know where to seek for the facts he may have temporarily mislaid; and if he really requires the aid Prof. Setchell is ready to render him in this respect, he is clearly unfit to teach.

"*On a Sunshine Holyday*." By the Amateur Angler. Pp. viii + 140. (London: Sampson Low, Marston, and Co., 1897.)

THE short—very short—papers collected in this booklet originally appeared in the *Fishing Gazette*. The author confesses that he is "well aware that from the standpoint of literature these papers possess no claim for a separate existence." He might also have added that, from a scientific point of view, there is even less justification for their publication.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Abridged Long Division.

A Brief Method of dividing a given Number by a Divisor of the Form ($h. 10^n \pm k$), *where at least* one *of the two numbers, h and k, is greater than* 1.

MY former paper on this subject, which appeared in NATURE for October 14, 1897, dealt only with the case where $k = 1$ and $k = 1$. It elicited, from other correspondents of NATURE, several interesting letters, which the editor kindly allowed me to see. One, from Mr. Alfred Sang, quotes Mons. L. Richard's "Sténarithmie," as containing my Rule for dividing by 11. Mons. Richard's book, which I had not previously met with, does certainly contain the rule, but the author has failed to see that the test, which this Method furnishes, for the correctness of the working, is absolutely *definite*. He says "La dernière difference, ou cette difference augmontée de 1, égalera le chiffre de gauche du nombre proposé." So ambiguous a test as this would of course be useless. But the "difference" he is speaking of is really the *last but one*: the very *last* will always (as I stated in my former paper) be equal to zero. Another correspondent, Mr. Otto Sonne, says that my Rules, both for 9 and for 11, are to be found in a school-book, by a Mr. Adolph Steen, which was published at Copenhagen in 1847. So I fear I must reduce my claim, from that of being the first to discover them, to that of being the first to publish them in English.

The Method, now to be described, is applicable to three distinct cases:—

(1) where $h > 1$, $k = 1$;
(2) where $h = 1$, $k > 1$;
(3) where $h > 1$, $k > 1$.

With certain limitations of the values of h, k, and n, this Method will be found to be a shorter and safer process than that of ordinary Long Division. These limitations are that neither h nor k should exceed 12, and that, when $k > 1$, n should not be less than 3: outside these limits, it involves difficulties which make the ordinary process preferable.

In this Method, two distinct processes are required—one, for dealing with cases where $h > 1$, the other, for cases where $k > 1$. The former of these processes was, I believe, first discovered by myself, the latter by my nephew, Mr. Bertram J. Collingwood, who communicated to me his Method of dealing with Divisors of the form $(10^n - k)$.

In what follows, I shall represent 10 by t.

Mr. Collingwood's Method, for Divisors of the form $(t^n - k)$, may be enunciated as follows:—

"To divide a given Number by $(t^n - k)$, mark off from it a period of n digits, at the units-end, and under it write k-times what would be left of it if its last period were erased. If this number contains more than n digits, treat it in the same way; and so on, till a number is reached which does not contain more than n digits. Then add up. If the last period of the result, *plus* k-times whatever was carried out of it, in the adding-up, be less than the Divisor, it is the required Remainder; and the rest of the result is the required Quotient. If it be not less, find what number of times it contains the Divisor, and add that number to the Quotient, and subtract that multiple of the Divisor from the Remainder."

For example, to divide 8678159248570315276409 2 by 9993 (*i.e.* by $t^4 - 7$), he would proceed thus:—

```
9993 || 867 8159 2485 7031 5276 | 4092
            6074 7114 7399 9220   6932
               4 2522 9803 1799   4540
                    29 7660 8622  2593
                        208 3626  0354
                            1458  5382
                               1  0206
                                     7
Quot. 868 4238 2153 2104 0004 || 4106 + 14 = 4120 Rem.
```

The new Method will be best explained by beginning with case (3): it will be easily seen what changes have to be made in it when dealing with cases (1) and (2).

The Rule for case (3), when the sign is "–," may be enunciated thus:—

Mark off the Dividend, beginning at its units-end, in periods of n digits. If there be an overplus, at the left-hand end, less than h, do not mark it off, but reckon it and the next n digits as one period.

To set the sum, write the Divisor, followed by a double vertical: then the Dividend, divided into its periods by single verticals, with width allowed in each space for $(n + 2)$ digits. Below the Dividend draw a single line, and, further down, a double one, leaving a space between, in which to enter the Quotient, having its units-digit below that of the last period but one of the Dividend, and also the Remainder, having its units-digit below that of the last period of the Dividend. In this space, and in the space below the double line, draw verticals, corresponding to those in the Dividend; and make the last in the upper space double, to separate the Quotient from the Remainder.

For example, if we had to divide 5984407103826 by 6997 (*i.e.* $7. t^3 - 3$), the sum, as set for working, would stand thus:—

```
6997 || 5984 | 407 | 103 | 826
       Quot.     |     |     ||      Rem.
       ==============================
                 |     |     |
```

To work the sum, divide the 1st period by h: enter its quotient in the 1st Column below the double line, and place its Remainder above the 2nd period, where it is to be regarded as *prefixed* to that period. To the 2nd period, with its prefix, add k-times the number in the 1st Column, and enter the result at the top of the 2nd Column. If this number *is not* less than the Divisor, find what number of times it contains the Divisor, and enter that number in the 1st Column, and k-times it in the 2nd; and then draw a line below the 2nd Column, and add in this new item, deducting from the result t^n-times the number just entered in the 1st Column; and then add up the 1st Column, entering the result in the Quotient. If the number at the top of the 2nd Column *is* less than the Divisor, the number in the 1st Column may be at once entered in the Quotient. The number entered in the Quotient, and the number at the foot of the 2nd Column, are the Quotient and Remainder that would result if the Dividend ended with its 2nd period. Now take the number at the foot of the 2nd Column as a new 1st period, and the 3rd period as a new 2nd period, and proceed as before.

The above example, worked according to this Rule, would stand thus:—

```
                  6      5      3
6997 || 5984 |  407 |  103 |  826
Quot.    855 |  281 |  849 || 6373 Rem.
       =============================
         854 | 8969 | 5946 |
           1 |    3 | ---- |
             | ---- |  849 |
             | 1972 |
             | ---- |
             |  281 |
```

the Mental Process being as follows:—

Divide the 5984 by 7, entering its Quotient, 854, in the 1st Column, and placing its Remainder, 6, above the 2nd period. Then add, to the 6407, 3-times the 854, entering the result in the 2nd Column, thus. "7 and 12, 19." Enter the 9, and carry the 1. "1 and 15, 16." Enter the 6, and carry the 1. "5 and 24, 29." Enter the 9, and carry the 2, which, added to the prefix 6, makes 8, which also you enter. Observing that this 8969 *is not* less than the Divisor, and that it contains the Divisor *once*, enter 1 in the 1st Column, and 3-times 1 in the 2nd, and then draw a line below, and add in this new item, remembering to deduct from the result 7-times t^3, *i.e.* 7000: the result is 1972. Then add up the 1st column, as far as the double line, and enter the result, 855, in the Quotient. Now take the 1972 as a new 1st period, and the 3rd period, 103, as a new 2nd period, and proceed as before.

The Rule for case (3), when the sign is "+," may be deduced from the above Rule by simply changing the sign of k. This will, however, introduce a new phenomenon, which must be provided for by the following additional clause:—

When you add, to the 2nd period with its prefix, $(-k)$-times the number in the 1st Column, *i.e.* when you *subtract* k-times this number *from* the 2nd period with its prefix, it will sometimes happen that the subtrahend exceeds the minuend. In this case the subtraction will end with a *minus* digit, which may be indicated by an asterisk. Now find what number of Divisors must be added to the 2nd Column to cancel this *minus* digit, and enter that number, marked with an asterisk, in the 1st Column, and that multiple of the Divisor in the 2nd; and then draw a line below the 2nd Column, and add in this new item.

As an example, let us take a new Dividend, but retain the previous Divisor, changing the sign of k, so that it will become 7003 (*i.e.* $7.\ t^3+3$). The sum, as set for working, would stand thus:—

```
7003 ‖ 6504 | 318 | 972 | 526
Quot.             |     ‖     Rem.
            |     |     |
```

After working, it would stand thus:—

```
                     1       4       5
7003 ‖ 6504   |    318 |   972 |   526
Quot.  928    |    790 |   371 ‖  4413 Rem.
       929    |  2*531 |  2602 |
        1*    |  7 003 |       |
              |  ----- |   371 |
              |  5 534 |
              |  ----- |
              |    790 |
```

the Mental Process being as follows:—

Divide the 6504 by 7, and enter the Quotient, 929, in the 1st Column, and the Remainder, 1, above the 2nd period. Then subtract, from the 1318, 3-times the 929, entering the result in the 2nd Column, thus. "27 from 8 I ca'n't, but 27 from 28, 1." Enter the 1, and carry the borrowed 2. "8 from 1 I ca'n't, but 8 from 11, 3." Enter the 3, and carry the borrowed 1. "28 from 3 I ca'n't, but 28 from 33, 5." Enter the 5, and carry the borrowed 3. "3 from 1, *minus* 2." Enter it, with an asterisk. Observing that, to cancel this *minus* 2, it will suffice to add *once* the Divisor, enter a (−1) in the 1st Column, and 7003 in the 2nd; and then draw a line below the 2nd Column, and add in this new item: the result is 5534. Then add up the 1st Column, and enter the result, 928, in the Quotient. Now take the 5534 as a new 1st period, and the 3rd period, 972, as a new 2nd period, and proceed as before.

The Rules for case (2) may be derived, from the above, by making $k=1$; and those for case (3) by making $h=1$. I will give worked examples of these; but it will not be necessary to give the Mental Processes.

By making $k=1$, we get Divisors of the form $(h.t^n \pm 1)$: let us take $(11t^4-1)$ and $(6t^5+1)$.

```
                      9         10         4
109999 ‖ 107523 |   8168 |    9662 |   0985
   Quot.   9774 |   9813 |    0861 | 41846 Rem.
           9774 | 107942 |  119474 |
                | ====== |       1 |
                |   9812 | ------- |
                |      1 |    9475 |
                |        | ======= |
                |        |     861 |
```

```
                      3                    3
600001 ‖ 7239 |  51798  |  2 6004 |   13825
  Quot.  1206 |  58431  |  9 4595 ‖ 219230 Rem.
              | 350592  | 4*7572  |
              | ======  | 60 0001 |
              |  58432  | ------- |
              |     1*  | 56 7573 |
              |         | ======= |
              |         |  9 4595 |
```

In this last example, there is no need to enter the Quotient, produced by dividing the 7239 by 7, in the 1st Column: we easily foresee that the number at the top of the 2nd Column *will be* less than the Divisor, so that there will be no new item in the 1st: hence we at once enter the 1206 in the Quotient.

By making $h=1$, we get Divisors of the form $(t^n \pm k)$: let us take (t^4-7) and (t^5+12).

```
9993 ‖ 867 |  8159 |  2485 |  7031 |  5276 | 4092
Quot.  868 |  4238 |  2153 |  2104 |  0004 | 4120 Rem.
       867 | 14228 | 32130 | 22088 | 19990 |
         1 |     7 |    21 |    14 |    14 |
           | ----- | ----- | ----- | ----- |
           |  4235 |  2151 |  2102 |     4 |
           |     3 |     2 |     2 |
```

```
100012 ‖ 7185 |  6 2039  |   10327 | 53118
         7184 |  7 5822  |   00463 | 47562
         7185 |  3*5819  | 9*00355 |
           1* | 10 0012  | 9 00108 |
              | -------- | ------- |
              |  7 5831  |     463 |
              |      9*  |
```

The first of these two sums is the one I gave to illustrate Mr. Collingwood's Method of working with Divisors of the form (t^n-k).

It may interest the Reader to see the 3 Methods of working the above example—ordinary Division, Mr. Collingwood's Method, and my version of it—compared as to the amount of labour which each entails in the working:—

	Ordinary Division.	Mr. C.'s Method.	My version of it.
Digits written:	202	82	44
Additions, or Subtractions:	204	97	25
Multiplications:	0	70	22

I am assuming that any one, working this example by ordinary Division, would begin by making a Table of Multiples of 9993, for reference: so that he would have *no* Multiplications to do. Still, the great number of digits he would have to write, and of Additions and Subtractions he would have to do, involving a far greater risk of error than either of the other Methods, would quite outweigh this advantage.

By whatever process a Question in Long Division has been worked, it is very desirable to be able to test, easily and quickly, the correctness of the Answer. The ordinary test is to multiply together the Divisor and Quotient, add the Remainder, and observe whether these together make up the given Number, as they ought to do.

Thus, if N be the given number, D the given Divisor, Q the Quotient, and R the Remainder, we ought to have

$$N = D.Q + R.$$

This test is specially easy to apply, when $D=(h.t^n \pm k)$; for then we ought to have

$$\begin{aligned} N &= (h.t^n \pm k).\ Q + R; \\ &= (hQ.t^n + R) \pm kQ. \end{aligned}$$

Now $hQ.t^n$ may be found by multiplying Q by h, and tacking on n ciphers. Hence $(hQ.t^n + R)$ may be found by making R occupy the place of the n ciphers. If R contains less than n digits it must have ciphers prefixed; if more, the overplus must be carried on into the next period, and added to hQ.

Having found our "Test," viz. $(hQ.t^n + R)$, we can write it on a separate slip of paper, and place it below the working of the example, so as to come vertically below N, which is at the top. When the sign in D is '−,' we must add kQ to N, and see if the result $= T$; when it is '+,' we must add kQ to T, and see if the result $= N$.

Now it has been already pointed out that when, in the new Method, the 1st and 2nd Columns have been worked, the 1st period of the Quotient and the number at the foot of the 2nd Column are the Quotient and Remainder that would result if the Dividend ended with its second period. Hence the Test can be at once applied, before dealing with the 3rd Column. This constitutes a very important new feature in my version of Mr. Collingwood's Method. Every two adjacent columns contain a separate Division-sum, which can be tested *by itself*. Hence, in working my Method, as soon as I have entered the 1st period of the Quotient, I can test it, and, if I have made any mistake, I can correct it. But the hapless computator, who has spent, say, an hour, in working some gigantic sum in Long Division—

whether by the ordinary process or by Mr. Collingwood's Method—and who has chanced to get a figure wrong at the very outset, which makes every subsequent figure wrong, has no warning of the fatal error till he has worked out the whole thing "to the bitter end," and has begun to test his Answer. Whereas, if working by *my* Method, he would have been warned of his mistake almost as soon as he made it, and would have been able to set it right before going any further.

As an aid to the Reader, I will give the Mental Process in full, for the 2nd and 3rd Columns of the first of the examples worked above.

The Divisor is 6997 (where $h = 7$, $k = 3$). Here you are supposed to have just entered the 281 in the Quotient. The Dividend, for these 2 Columns, is 1972 | 103; the Quotient is 281, and the Remainder 5946. The Test is $hQ.t^n + R$, ($i.e.$ $7 \times 281000 + 5946$), the Mental Process being as follows. You write, on a separate slip of paper, the last 3 digits of R, viz. 946, and carry the 5 into the next period, adding it to the 7 × 281: thus. "5 and 7, 12." Enter the 2, and carry the 1. "1 and 56, 57." Enter the 7, and carry the 5. "5 and 14, 19." Enter it. Having got your Test, try whether $(N + kQ)$ is equal to it. This you compute, comparing it with your Test, digit by digit, as you go on, thus. "3 and 3, 6." Observe it in the Test. "0 and 24, 24." Observe the 4, and carry the 2. "3 and 6, 9." Observe it. "1972 and 0, 1972." Observe it. The Test is satisfied.

6	5
407	103
281	
8969	5946
3	
1972	
281	
Test 1972	946

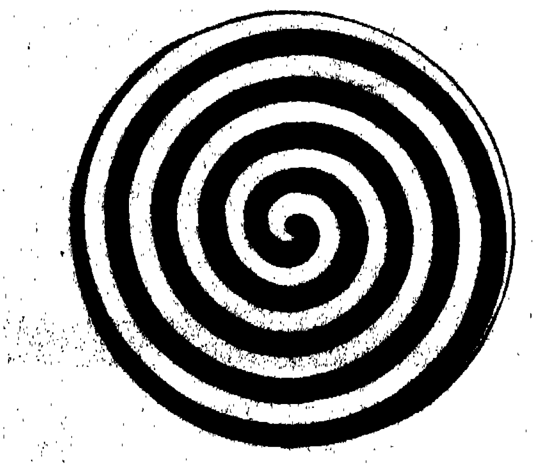
For Divisors of the form $(t^n \pm k)$ there is no need to write out the Test: the numbers, which compose it, already occur in the working, and may be used as they stand.

CHARLES L. DODGSON.

Ch. Ch., Oxford, December 21, 1897.

Optical Illusions produced by Observation of Rotating Spirals.

IT is well known that if a spiral, such as represented in the figure, rotating in the opposite direction to the movement of the hands of a clock, be observed for some minutes, an impression of circles arising at the centre and disappearing at the periphery is produced; after protracted observation, on looking at printed matter or a person's face, the letters appear to move towards the centre while the face appears to become smaller and recede. If the spiral be rotated in the opposite direction, the circles appear to be passing towards the centre, in which case the after-effect is more marked and lasts longer, the letters naturally pass centrifugally while the face apparently increases in size.



The latter effect in my own observations has sometimes continued for fifty seconds, while the former never for more than twenty seconds. This effect is practically the same as the "waterfall phenomenon," in which case the banks appear to move upwards after gazing for some time at the falling water.

What I wish to draw attention to in this note is the effect which may be observed on closing the eyes after watching a well-illuminated rotating spiral.

If the direction of rotation has produced the impression of centripetally travelling rings, a star composed of radial lines consisting of small granular patches of light passing centrifugally will be noted for a second or two after closing the eyes. The granules pass centripetally if the direction of rotation be reversed. The star will appear symmetrical if the spiral be viewed normally, but if sideways the lines composing it will be curved and the star distorted: to some observers the centre of the star always appears to be further distant than the periphery. I have not been able to find any difference in time of duration of this after-image on rotating the spiral in the two directions.

The colour of the granules is always yellowish, whatever be the colour of the spiral and background. It is interesting to note that, as a rule, after-images of central production can be prophesied on psychological reasoning; while in the above case no one to my knowledge has been able to foretell the appearance of the star, and therefore I am inclined to think that the effect is retinal.

O. F. F. GRÜNBAUM.

Poisonous Koda Millet.

THERE have been several well-ascertained examples of poisoning from diseased or improperly-prepared *Koda* millet (*Paspalum scrobiculatum*) during the past year in India. Owing to the prevailing scarcity of the usual food-grains, it is probable that *Koda* millet has been extensively sold and eaten in localities where its use is ordinarily unknown.

I hoped to undertake an investigation myself into this matter, which is one of great importance both from the hygienic and economic points of view. After consultation, however, with Surgeon-Major van Geyzel, chemical examiner to the Government of Madras, I have decided that any investigation worthy of the name would occupy far more time than I have to give to it. I therefore write to you with a view to eliciting the help of some worker in Britain or elsewhere who has the necessary leisure and facilities for work of this sort. I have samples of the grain, husked and unhusked, from different localities, and can supply the necessary references to the literature of the subject. The investigation, I take it, would have to be of a chemico-biological nature, and would be most appropriate, say, for a thesis, or in connection with some fellowship. I hope that some one who can carry the work right through, and will ascertain the exact source and constitution of the poison (? a volatile alkaloid), will write to me at the address given below. In another ten years, perhaps, there will be some attempt to provide the men and the facilities for such work, even in India, when the Victoria Institute is an accomplished fact.

A. E. GRANT.

Hygiene Laboratory, Medical College, Madras.

Hermaphroditism in the Herring.

I WISH, with your permission, to record a singular "freak of nature" and, at the same time, to ask whether any similar observation has been made by others.

Some fresh herrings were served us here last evening for dinner, and among them was one which, on being opened, disclosed a roe, half of which was "hard" and the other half "soft." The ova and milt were respectively quite normal in appearance (and flavour), and melted imperceptibly one into the other about midway in the length of the roe, which was, itself, in an obviously natural and undisturbed condition.

Sea Lawn, Torquay, January 12. DAN. PIDGEON.

A Bright Meteor.

ON Sunday night (December 12), at about 8.15, I witnessed the appearance of a magnificent meteor which seemed to travel from the south-east in the direction of Ursa Major. It broke up into a number of fiery balls of most brilliant colours. The atmosphere was clear and frosty and the moon very bright, but it was for the moment quite eclipsed by the brilliancy of this striking meteoric display. This may be the same phenomenon as that referred to in NATURE for January 6 (see page 228). I did not hear any sound like thunder at the time.

SUSANNA LEHMANN.

RECENT SEISMOLOGY.[1]

II.—UNFELT MOVEMENTS OF THE EARTH'S CRUST.

THE records obtained from seismographs often showed, as we have already explained, preliminary vibrations performed with a rapidity which has even reached fifteen complete back and forth movements per second, a shock or shocks, and lastly a number of irregular jolts or undulations which died away with an increasing period. What seismologists had captured was what they could feel, and they were left to speculate as to what came at either extremity of the seismic spectrum. It seemed tolerably certain that if instruments were constructed capable of responding to exceedingly rapid but minute elastic vibrations, then a seismogram might show the movements preceding but forming portions of the preliminary vibrations. These would accompany the sound waves which in rocky districts so commonly outrace movements of a more pronounced character. These sound phenomena, which never extend far beyond an epifocal area, are in certain districts isolated phenomena which frequently recur. Without calling up the "spooks of Ballechin," or the Ghost of Long Wittenham, which on New Year's Eve rapped on the walls of many houses, in two instances we are assured that they have been sufficient to explain noises which had been regarded as supernatural, and it is not unlikely that the fully-equipped ghost hunter may be the discoverer of new paths in seismic science. When a volcano explodes, the resultant vibrations to which ordinary seismographs or ourselves are sensible, seldom reach to any great distance; but is it not possible that elastic tremors, the result of a powerful impulse, may even reach and be focussed at the antipodes of their origin? In the Perry-tromometer we have an apparatus which will automatically record elastic vibrations of the order here considered, but up to the present we are without the observer who is able to isolate himself at a site suitable for its installation. In the Isle of Wight the writer found that this instrument recorded the firing of cannon at a distance of six miles, the movements of trains at a distance of nearly one mile, the rumbling of carriages at the distance of a quarter of a mile, whilst it kept an excellent tally of the back and forth journeys of eleven gravel carts worked by a neighbouring contractor.

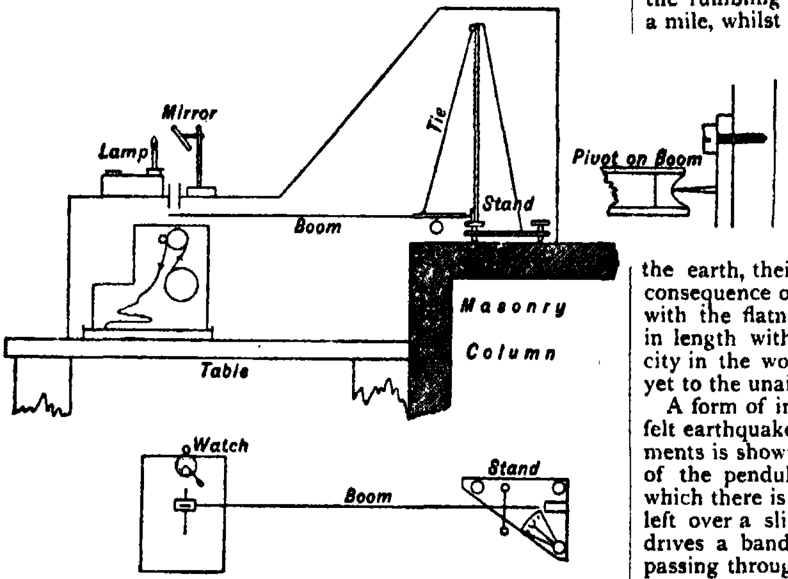

FIG. 7.—Type of instrument adopted by the Seismological Investigation Committee of the British Association, and established at many stations round the world. (Milne.)

Investigations on the other end of the seismic spectrum have been more successful, and we now know that waves which have a period of one or two seconds within the area where they are appreciable to the senses, after these have radiated to great distances, for example over or through a quadrant of the earth, their period may exceed twenty seconds. In consequence of the slowness of the movements, together with the flatness of the waves, which are probably miles in length with heights measured by a few inches, every city in the world is often rocked slowly to and fro, and yet to the unaided senses motion is imperceptible.

A form of instrument used by the writer to record unfelt earthquakes, diurnal waves, tremors and other movements is shown in Fig. 7. On the outer end of the boom of the pendulum there is a small aluminium plate in which there is a slit. This is free to float to the right or left over a slit in the lid of a box in which clockwork drives a band of bromide paper. Light from a lamp passing through the two crossed slits reaches the paper as a point, and gives a line with extremely fine definition (see Fig. 8, under the words September 21). At each half-hour the minute hand of a watch crosses one end of the slit, and by eclipsing the light gives the hour marks shown in Fig. 8.

In the photograms of these unfelt earthquakes we see that the duration of the preliminary tremors is apparently connected with the distance the disturbance has travelled, and in this way a record has impressed upon it what is partially equivalent to the post-mark of its origin. For example, a disturbance originating in Japan would at a distance of, say, 200 km., be heralded by tremors which an ordinary seismograph would show to have a duration of ten or twenty seconds. A seismogram of the same shock taken in Europe shows that the same movements have a duration of about half an hour. The maxima phases of movements, which may be waves of distortion modified by gravity, travel at approximately

FIG. 8.—This earthquake of September 21, 1897, as recorded in the Isle of Wight, shows preliminary tremors of about 43 minutes, which indicate an origin at a distance of 112°, say, east of Borneo. It disturbed magnetographs in Batavia. A similar earthquake ten hours earlier is not known to have done so. (Milne.)

---

[1] Continued from p. 249.

the same rate of 2 or 3 km. per second over paths which are long or short. The preliminary vibrations, in all likelihood representing waves of compression, appear to have velocities of propagation closely related to the length of the path as measured on an arc over or across which they have been propagated. Such figures as we have, which are open to correction after observations have been extended, are easily remembered. Starting with a velocity of 2 km. per second for a path of 2000 km., then for a path of 4000 km. the velocity would be 4 km. per second, from Japan to England, or 9000 km., the velocity would be 9 km. per second; whilst, if we may carry conclusions beyond the limits of observation, we may imagine that the velocity of propagation between an origin and its antipodes may be 18 km. per second. As Mr. J. Larmor pointed out, if our records are correct, then outside our first 2000 km. coseismal, great disturbances will be recorded at all points on the surface of the world at approximately the same instant. Undoubtedly velocities of 9 and 10 km. per second have been noted, which indicate that the preliminary vibrations, at least, can not have been transmitted round the heterogeneous and broken materials constituting the earth's crust, but rather, that the movements have passed along direct, or by refraction along curvilinear paths *through* the interior of our earth. This fact, taken in conjunction with the fact that velocities of transmission increase with an increase in the length of the wave path, and that at any given station two sets of vibration separated by a time interval proportional to the difference in the great circle distances between an epicentre and the point of observation have not been observed, tend to strengthen this same view.

Rules connected with the transmission of preliminary tremors which apparently promise to throw new light on the physical condition of the interior of the earth are—

(1) The velocity in kilometres per second with which these movements are propagated is equal to one-quarter of the square root of the mean depth of the chord or path (in kilometres) along which we may suppose they travelled.

(2) The duration of preliminary tremors, or the interval of time expressed in minutes by which they outrace the longer period waves (as shown on a seismogram), equals the square root of the mean depth of the supposed wave path expressed in kilometres.

These rules, taken in conjunction with a map showing the surface configuration of the globe, enable an individual observer not only to locate an origin but also to determine the time at which an earthquake originated.

Inasmuch as a Committee of the British Association have lent their weight to the establishment of a number of horizontal pendulums at various observatories around the world, within the next few years it is likely that our present knowledge of the seismic breathings of the earth's crust will be placed on a more extended and accurate basis than that on which it at present rests; and, amongst other things, we shall have accumulated new facts bearing upon the effective rigidity of our planet, which is evidently greater than that usually assumed.

The practical outcome of this work is already many-sided. Observers at magnetic observatories, like those at Kew, Potsdam and Batavia, are now aware that greater or less disturbances in the uniformity of their records sometimes accompany unfelt earth waves. Because the earth waves do not always leave a record of their occurrence, whilst there are magnetographs of the Kew type, as, for example, at Greenwich, Falmouth and Stonyhurst, which, so far as I can learn, are but very rarely disturbed, we can not say with certainty that the movements of magnetometers are altogether the effect of mechanical disturbance. At about 5 a.m. on September 21, very marked movements were recorded by the magnetographs in Batavia, evidently the result of a movement recorded in the Isle of Wight (see Fig. 8). Because the preliminary tremors have a duration of forty-three minutes, the distance of their origin from the south of England is probably about 112°. This, together with the fact that on this date a "slight tremor" was felt along the coast of North Borneo, makes it tolerably certain that the origin of this convulsion was one or two hundred miles from that island.* Strange to say, at 7 p.m. on the previous evening a disturbance, in all its main features identical with the one here illustrated, is also to be seen on the Isle of Wight seismograms, from which it may be inferred that we have the records of two earthquakes from the same origin.

Assuming this to be the case then, so far as we can judge from information received from Batavia, it was only the second of these unfelt motions that caused disturbances in the magnetographs at that place. Not only are magnetographs affected at the time when huge earth waves slowly move the areas on which they are situated, but in Japan similar instruments situated near to an earthquake centrum have been perturbed some days before the occurrence of a world-shaking shock. Then, again, there are the remarkable secular changes in declination and dip observed between 1880 and 1885, at several eastern stations, respecting which Captain E. W. Creak, F.R.S., gives the following notes:—

Bombay.—Until 1883–85 the needle was moving eastwards. It then stopped, since which it has been moving westwards at an increasing rate. In 1881 there was a sudden change in the dip, and the needle is now going down.

Hong Kong.—Until 1875 the needle was moving eastwards. Then there was a rest until 1880, when it turned westwards. The dip was upwards until about 1880, since which it has turned downwards.

Batavia.—Until 1884 the needle was moving eastwards, when it became stationary. It is now moving westwards. The dip was moderately upwards until 1881, but it has now greatly increased.

When it is remembered that these remarkable changes took place about the time of large earthquakes in Japan, as, for example, that which led to the inauguration of the Seismological Society in 1880, the Krakatoa eruption of 1883, and that the illustrations of more immediate possible connections between seismic and magnetic phenomena may be multiplied, we recognise that the seismic survey of the world may not only throw new light upon its physical condition, but also, perhaps, it may lead to inferences respecting gravitational rearrangements of external materials and internal magmas. The sites of these, at present, hypothetical hypogenic changes we should expect to find in districts where secular movements and superficial loading, due to sedimentation, are most pronounced. Because earthquakes are apparently the results of critical conditions in these processes, the records from horizontal pendulums tell us that the sites we search for are to be found submerged beneath deep water at or near the base of steeply sloping continental areas. The enormous size of the superficial displacements which accompany certain of these suboceanic changes is indicated by the creation of sea-waves, which have often agitated the whole of the Pacific for a period of one or two days; and if these rearrangements of material on the bed of an ocean are related to changes in the state of stress or accelerations in the movement of an internal *quasi* rigid matter influenced by continental load, we see in the operations which culminate as earthquakes, causes which should, at least, have a local magnetic influence.

Captain Creak, writing on "the general bearing of magnetic observations," in *Science Progress*, April 1896, says: "It may be remarked in passing that a remarkable alteration in the amount of secular change has been noticed in the declination and inclination at the following observatories: Bombay, Batavia and Hong Kong, about the period of the eruption of Krakatoa in 1883. This may be only a coincidence, but may it not also point to the possibility that the changes below the surface of the earth which culminated in that mighty explosion, and may still be at work, have had and continues to have magnetic effects which are recorded by the needles at these observatories?" (See also "The Volcanoes of Japan," by J. Milne, *Trans. Seis. Soc.*, vol. ix. part 2, p. 178, 1886.)

The seismograms of unfelt earthquakes tell the student of dynamical geology that certain activities to which he devotes attention are more pronounced beneath the ocean than they are on land, whilst the location of the origins from which these movements proceed indicate to the cable engineer districts to be avoided.

If we except the action of waves, the borings of teredo, and other influences resulting in cable destruction in shallow water, submarine earthquakes and their accompanying land-slides are responsible for very many interruptions of international communication. This form of destruction is particularly marked along the west coast of South America, and it is not unknown in the Atlantic, the Mediterranean, and the Indian Ocean. In 1888 a submarine earthquake cut off the Australian colonies from the outer world for a period of nineteen days, and the apprehension that the isolation was an act of war led to the calling out of military and naval reserves. Had Australia been provided with a single instrument to record the unfelt movements, which must have reached it, anxiety and expense would have been avoided.

From an official notification I learn that two West Indian cables gave way on December 31, 1897. I am not certain, but the Isle of Wight seismograms indicate that the failures probably took place at 11.30 a.m.. G.M.T., on December 29.

One immediate use of a seismogram is that it tells us whenever a large earthquake occurs, and gives a locus for its origin, which information has already on more than one occasion been the means of correcting, confirming, extending and disproving ordinary telegraphic information. Sometimes messages have reached us which have contained errors in their dates of one or two days, others have been grossly exaggerated accounts of small disturbances, whilst a third group, inasmuch as they create feelings of anxiety without reason are the most reprehensible of all, have, if we except the feelings of satisfaction they gave to their senders, been without foundation. In all these instances the seismogram or its absence has assisted in the interpretation of the telegram.

Up to the present seismology has found foster-parents in the meteorologist and the geologist—the one collecting facts about earthquakes, whilst the other wrote about them. Because it has grown to unwieldy proportions, it seems time that the child should try and stand alone and become guardian of its own discoveries. In "diurnal waves" and "tremors" we see Romulus and Remus seeking a mother, and although they are not of the *genus terræmotus*, because they partially, at least, represent earth-movements, Seismology has become their guardian.

By a diurnal wave we mean a slow tilting which takes place in piers and buildings, especially on fine days, for six or ten hours rapidly in one direction, and during the remainder of the twenty-four hours, but more slowly, in an opposite direction (Fig. 9). This movement may be found underground where changes in temperature are insignificant. The actual causes of these movements are at present matters for speculation, but the theory which best explains the phenomena they present (as for example, that on opposite sides of a valley, it has been observed that movements take place simultaneously but in opposite direction), is that these changes in the vertical are due to differential changes on opposite sides of a station in the loads removed during the day, or acquired during the night by evaporation and condensation of aqueous vapours. During the day it is assumed that, by ordinary evaporation and the transpiration of plants, the bottom of a valley loses more weight than its comparatively drier and less clothed sides.

During a hot day the stream at the bottom of such a valley should discharge fewer and fewer gallons of water, whilst the valley bed, because it is relieved of load, should rise. For the remaining fourteen or eighteen hours, because aqueous vapour is condensed beneath the chilled surface of the ground, or as it emerges from the ground on plant and other surfaces, the stream in the bottom of the valley would increase its flow, and relatively to the sides and bounding ridges of the valley, where we may suppose the conditions for condensation to be less favourable, the lower parts of the same would become heavier and thereby sink. As to whether this concertina-like opening and shutting of valleys representing changes of slope of one or two inches in three or four miles in the average inclination of their boundaries really exists, all we can say is that instruments have given indications that can be explained on such a supposition. The fact that the piers carrying some of the instruments have risen from the chalk, and not from the alluvium, and that during long-continued wet weather there is continuous creeping of a horizontal pendulum towards the heavily loaded valley bottom, and that the direction of greatest movement at the time of an earthquake appears to be at right angles to the dip, from which it may be inferred that valleys due to geotectonic folding exhibit a certain flexibility, tend to support the idea that the observed diurnal movements are due to actual movements of more or less extensive areas. No doubt some portion of the observed effects may be directly attributable to solar radiation.

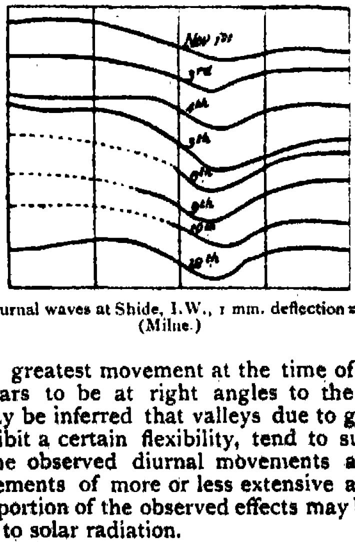

FIG. 9.—Diurnal waves at Shide, I.W., 1 mm. deflection = tilt 0″·5. (Milne.)

In searching for an explanation of diurnal, annual and other changes in the vertical, the seismologist has had to consult the records of the astronomer, the observations of the hydraulic engineer, the botanist, and the farmer, and to experiment and search for information in domains far removed from anything supposed to be connected with movements of the ground.

Have changes in the vertical been most pronounced in regions where it may be supposed that orogenic changes are yet in progress? How far are changes in the vertical effected by seasonal and daily changes in temperature, by fluctuations in barometrical pressure, by the rise and fall of tide upon a coast line, and by lunar attraction? What tilting effects would result if the seasonal growth and partial removal of foliage and herbage on one side of an observing station were greater than those upon the opposite side? What is the rate at which alluvium may creep down the face of steep slopes, carrying with it perhaps a forest, and what is its cause? What is the amount of moisture transpired by various plants per day, per month, and per season? Do not some plants and trees absorb rather than transpire moisture from the atmosphere at certain seasons? What is the transpiration of plants at night as compared with that during the day? Is there such a thing as subsurface dew, and what is its amount? What is the function of stones in arable land as fertilisers? What do we know respecting the diurnal flow in rivers, and the semi-diurnal rise and fall in certain wells? Will a squad of men walking up to the walls of an observatory, or the load equal to the weight of an average man at the base of a pier in the same produce any appreciable change of level on the top of such a pier? Are high mountains measurably deflected by wind pressure? In the workings of a mine beneath the sea what data do we possess respecting deflections in the roof due to the rise and fall of a superincumbent tide? What is the natural period of vibration of a chimney or building of given structure?

These are examples of the varied questions which have been placed before the seismologist, and to most of which, as the result of experiment and observation, he is able to give fairly definite replies. Although in a few instances these replies may not have given the assistance to his investigations expected, a consolation remains that they have been of considerable value to workers in other fields.

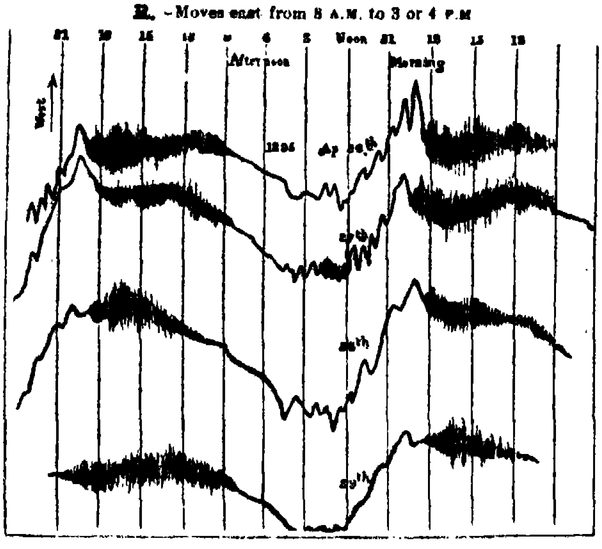

FIG. 10.—Irregular diurnal waves in Japan, always showing tremors from 9 p.m. to 6 a.m. (Milne.)

Perhaps the greatest trouble against which the working seismologist has had to fight have been the ubiquitous, so-called, "earth" tremors (see Fig. 10). Sometimes the apparatus will swing, and perform for hours or days various irregular, and sometimes marvellously regular back and forth movements, with the result that all traces of important phenomena have been eclipsed (Fig. 11). Not only do "tremors" affect finely constructed horizontal pendulums, but in all probability they affect magnetographs, the delicate balance of the assayer, and accelerate or retard the swing of pendulums. They are frequent in winter, at night, and whenever the observatory in which they are recorded is crossed by a steep barometric gradient. They are particularly noticeable with a frost and a falling thermometer. With a howling gale, and even during a typhoon, when buildings shake and shudder, they are as likely to be absent as present (Fig. 12).

Because a light horizontal pendulum is more disturbed than one that is heavy, and that we observe at one station tremors are marked, whilst they are only shown feebly, or are entirely absent at another station a few yards distant, it is evident that we are dealing with movements due to currents of air, rather than with movements due to tremors in the ground. Although we fully recognise, as stated at the commencement of this article, that there are microseismic movements in the earth, it is very doubtful whether in the thousands of observations carried out day and night, especially in the Italian peninsula, these movements have been differentiated from those which are the result of atmospheric circulation. Simply opening or closing the door of a case covering an instrument will sometimes start or stop a so-called tremor storm. The fact that placing a tray of calcium chloride inside one of these cases will cause very large and continuous movements which cease on its withdrawal, indicates that air currents are partly due to the manner in which an atmosphere becomes dry or moist. In the search for the originating cause of tremors which has extended over a period of nearly thirty years, we see an excellent example of long-continued and patient work which, so far as the advancement of seismology is concerned, appears at first sight to have terminated in a fiasco. Now, however, we know that we have to distinguish between movements caused by the atmosphere and those coming from the earth. We see a reason why at particular observatories magnetographs are sometimes on the swing. The reason why,

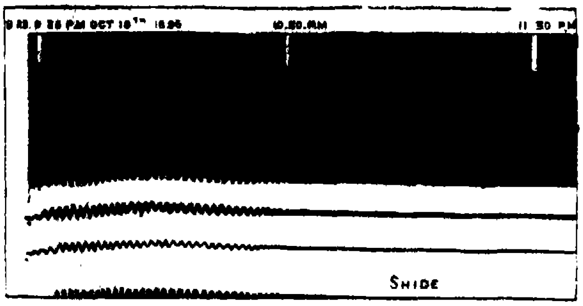

FIG. 11.—Pulsations or very regular tremors with periods of 2 or 3 minutes. The recording pendulum has always a natural period of about 15 seconds. (Milne.)

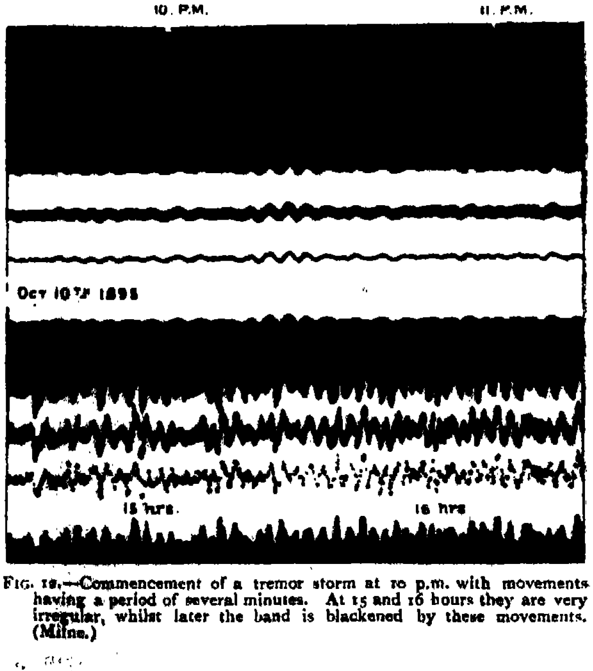

FIG. 12.—Commencement of a tremor storm at 10 p.m. with movements having a period of several minutes. At 15 and 16 hours they are very irregular, whilst later the band is blackened by these movements. (Milne.)

under certain conditions, the assayer's balance may sometimes oscillate and quickly change its zero is understood. Possibly these air currents may indirectly have led to the abandonment of the Cavendish experiment at Cambridge, and explain why a very well-constructed horizontal pendulum is never quite at rest.

One very important piece of knowledge for the seismologist lies in the fact that these so-called tremors can be stopped by using covering cases through which air can circulate, but above all by working in a room that is almost draughty with ventilation. Sometimes a room will be found which it seems impossible to cure, whilst in the adjoining one, for reasons not quite clear, the same instrument will always remain at rest.

It seems as if there existed in rooms which may be fairly similar in appearance slight physical differences of the walls, the floors and ceilings, as, for example, with regard to dampness; so that in one room, in consequence of differences of temperature, power of desiccation and other properties between the different boundaries, we may have a slow circulation of air established which is inappreciable in an adjoining room. Whether this is the true explanation of the seismic bogey remains for more careful demonstration, but already the writer has learned that with draughty surroundings an instrument will remain at rest, whilst when this condition is neglected, what is apparently a slow and steady circulation of the atmosphere will cause motion. We yet wish to know why these troublesome visitors appear with such regularity at certain hours and seasons (see Fig. 9). One result of what we have learned is that now hundreds of feet of bromide paper have been saved from blackening, and unfelt earthquakes, which otherwise would have been eclipsed, have been clearly recorded.

In the above few notes all that is attempted is to give a scanty outline of the more important branches of work which at present attract the attention of the working seismologist. Other investigations which it is desirable to make relate to the irregular changes in level which are completed in a few minutes or several days, and above all those grander movements, the results of which are exhibited on the surface of our earth in the formation of continental domes and mountain ranges, together with those activities hidden from our view, which have been referred to as processes of secular flow and crush—in all of which we see the parentage of the earthquake.

J. MILNE.

THE CAMBRIDGE EXPEDITION TO TORRES STRAITS AND BORNEO.

DURING the preparation of a monograph on the anthropology of the Torres Straits islanders, I found the notes I had previously made were unsatisfactory on so many points that I decided to go out again in order to render them as complete as possible, though probably a great deal is by this time irretrievably lost.

A Committee of prominent members of the University of Cambridge is co-operating with me, and part of the cost of the expedition will be defrayed by a grant from the Worts' Fund, which is administered by the University.

The expedition will be almost entirely anthropological in character, but the land flora and fauna will not be neglected, and certain geographical observations will also be made.

The other members of the expedition are Dr. W. McDougall, Fellow of St. John's College, Cambridge, and of St. Thomas's Hospital, London; Dr. C. S. Myers, Caius College, Cambridge, and St. Bartholomew's Hospital, London; Mr. S. H. Ray, Dr. W. H. R. Rivers, St. John's College, Cambridge, Lecturer on Experimental Psychology at Cambridge and at University College, London; Dr. C. G. Seligmann, of St. Thomas's Hospital; and Mr. A. Wilkin, of King's College, Cambridge.

The work of the expedition will be distributed as follows:—I shall be responsible for the observations on the physical characters of the natives; their language and phonology will be studied by Mr. Ray. Mr. Ray, who has a world-wide reputation as an authority on the languages of Oceania generally, has already made a very careful study of the languages of Torres Straits ("A Study of the Languages of Torres Straits, with Vocabularies and Grammatical Notes," *Proc. Roy. Irish Acad.* (3), ii., 1893, p. 463; iv., 1897, p. 119). Drs. Rivers, McDougall and Myers will initiate a new departure in practical anthropology by studying comparative experimental psychology in the field. They will test the senses and sensibility of the natives as far as it will be possible under the local conditions, and make whatever observations they can on the mental processes of the natives. Dr. Myers will also pay especial attention to native music, and I shall continue my researches on the decorative art of British New Guinea.

The hygienic and medical aspects of anthropology will be studied by the four qualified medical men. The sociology of the natives, including such subjects as relationships, ownership, land tenure, descent of property, and the like, will be investigated by Mr. Wilkin. All the old legends that can be collected will be recorded, and an endeavour will be made to recover the old beliefs of the people. Other departments of anthropology will also be studied. Dr. Seligmann will act as naturalist to the expedition; one of his duties will be to identify all the animals and plants which are utilised by the natives in any way.

Besides the ordinary instruments for anthropometry, there will be a small, carefully selected, collection of apparatus for experimental psychology. Two mechanical phonographs will be taken to record the native songs, music and languages. There will also be a complete photographic equipment, including a cinematograph for reproducing native dances, ceremonies, and certain characteristic actions.

The main object of the expedition is to continue and, as far as practicable, complete the earlier observations made in Torres Straits; but, for the sake of comparison, it is hoped that observations will be made on Australians, Papuans, Melanesians and Polynesians, as opportunities present themselves. After spending a few months in the Straits a short visit will be paid to the mainland of New Guinea, in order to trace the relationship of the islanders.

Some of the party will then have to return home; but the remainder have accepted a very generous and enthusiastic invitation to visit Mr. C. Hose, the Chief Magistrate of the Baram District of the Raj of Sarawak. Mr. Hose, who is a Cambridge man (Jesus College), is a keen naturalist and has a very wide knowledge of the natives and their languages, and has a warm sympathy for the people themselves; consequently the expedition will have exceptional facilities for seeing something of the inland tribes of Borneo, and interesting comparisons may be expected between the different races which the expedition will have under observation.

The expedition will start about March 2, and will return early in the summer of 1899.

Any suggestions as to lines of investigation or methods of study will be gladly welcomed. If the curator of any museum or collection desires information respecting ethnographical objects from Torres Straits or British New Guinea, and sends sketches or photographs of such objects to me (Inisfail, Hills Road, Cambridge; or Thursday Island, Torres Straits, Queensland), I will take the illustrations with me, and will endeavour to obtain the required information at the spot where the objects were obtained. I shall also be pleased to make, as far as I am able, any special inquiries that any ethnologist may require.

ALFRED C. HADDON.

MINE ACCIDENTS IN 1897.

WITH commendable celerity the Home Office has issued, in the form of an advance proof, the tables of accidents and deaths at the Mines and Quarries of the United Kingdom last year. Six foolscap pages closely printed with figures are not likely to attract the ordinary reader; but if they are carefully scanned, several important facts come to light. The Diamond Jubilee year is remarkable for its small death-roll from explosions of fire-damp, as there were but twelve fatal accidents and only nineteen deaths. Probably such a happy result has not been known this century; at all events since 1851, when official statistics first began to be kept, the number of explosions has been gradually diminishing in the most satisfactory manner, and though several great disasters, each involving a loss of more than a hundred lives, have happened of late years, the total number of deaths from explosions has decreased, in spite of the enormous rise in the output of coal. According to the official statistics, the annual number of victims by explosions of fire-damp and coal-dust for the last forty-seven years has only in seven cases been fewer than 100, and in no case less than 49 until last year. Far less satisfactory is the death-roll from falls of ground; this shows no signs of diminution; on the contrary, we find 485 deaths against 439 in the previous year. How long is this state of things to continue? Why do falls happen? The reply is "From want of supports," and the self-evident remedy which suggests itself is "systematic timbering." The German Government has taken the matter in hand by appointing a special Commission to report upon means of preventing accidents from falls of ground. Are we to wait until this Report is issued before grappling with the question? The dangers of fire-damp and coal-dust have now been dealt with by Statutes; and the worst death-trap in the mine should also receive in its turn some special legislative attention?

Shaft accidents are diminishing in number in a way that makes the shaft nowadays almost the safest place in the mine. The miscellaneous accidents, most of which are put down to haulage, are still numerous. It is curious to note, while dealing with fatalities from miscellaneous causes, that the worst mining disaster in the British Isles last year happened at a lead mine and not at a colliery, for an underground fire claimed twenty victims. On the whole, there were 972 persons killed by accidents at mines in this country last year, compared with 1065 in 1896. This is a decrease of ninety-three deaths. How far this is a real improvement cannot be stated until the statistics of persons employed have been collected, so as to enable the death-rate to be calculated.

The final tables tell us that 123 persons were killed at the quarries of the United Kingdom which are included by the Quarries Act, from being more than 20 feet deep. There is a decrease of one death compared with 1896.

The statistical matter has been set up this year in an improved and far more convenient fashion, for the figures can now be read without twisting round the pages sideways.

THE PROPOSED MIDLAND UNIVERSITY.

EDUCATIONAL authorities throughout the country cannot but rejoice in the important speech which Mr. Chamberlain made in Birmingham on Thursday last. A recent Act of Parliament has been passed whereby the Mason College has been made a University College, governed by a representative court of governors, and it was in his new capacity of President of the Mason University College that Mr. Chamberlain took the opportunity of formally launching the scheme for the creation of a great University of the Midlands. The idea of a Midland University has been under consideration for several years past, and with the strong support now promised by Mr. Chamberlain, Birmingham may confidently look forward to shortly becoming the proud possessor of what London has been struggling in vain so many years to obtain—a great teaching University depending for its position and authority not on traditions, but founded in harmony with modern requirements, in sympathy with the scientific and educational needs, and aspirations of the day.

Prof. Mahaffy, a few weeks ago, humorously represented some of the objections which have been raised to the establishment of a new University in Birmingham by remarking, "Oxford I know, Cambridge I know; but who are ye?" Mr. Chamberlain, however, has met and anticipated such and similar flimsy protests by at once, in his characteristic manner, going to the root of the matter. "The new University cannot in any sense be a competitor with the old Universities of Oxford and Cambridge . . . they offered associations, traditions, and conditions which it could not, under any circumstances, attempt or hope to emulate. Therefore, whilst they could not imitate Oxford and Cambridge if they would, he would say also that they *would not if they could* . . . because when they came to create new Universities in this modern time, and under modern conditions, it was something rather different they had in view." It cannot be sufficiently recognised that whilst traditions may be, and often are, a power for good, a slavish and blind adherence to them may also work incalculable mischief in society. It is not too much to say that the great University Colleges which have grown up in all parts of the country during the latter half of the present century, have been not a little hampered in their work, not a little shorn of the recognition due to them by being, in some respects, overshadowed by the older Universities. The splendid scientific work, however, which has emanated from these too frequently derided and belittled Provincial Colleges is gradually bringing about a change in public opinion. The munificent support which has recently been accorded to the Owens College, Manchester, and the attitude which so distinguished a statesman as Mr. Chamberlain has taken up with regard to the proposed Midland University, are auguries that a new era is commencing, when the public are beginning to realise what has been and still remains to be done by modern Universities unhampered by local traditions, in touch with the time, and animated with enthusiasm not only for the communication of knowledge, but for the advancement of learning by the prosecution of original researches. There is one point to which we venture to hope those entrusted with the great task of building up this new University will give due weight, and that is the study of modern languages. We as a nation are far behind Germany, for example, in the importance which we attach to the acquirement of foreign tongues, and our trade, we have often been told, suffers in consequence. Let Birmingham set the example, and in addition to thoroughly equipping its faculties of science, art and medicine, let it have the honour of establishing a great school of modern languages. Educationists in this country, who for years have been vainly endeavouring to obtain an effectual hearing for the need of harmonising modern scientific education not only with the requirements of the time, but with the advance in science, owe Mr. Chamberlain a debt of gratitude for his address, of which we give the following abstract from the *Times* report:—

> The new governing body of the College were entertained at luncheon in the Council-house by the Lord Mayor (Mr. C. G. Beale), who proposed the toast of "Mason University College," which was coupled with the name of the president, Mr. Chamberlain.
>
> Mr. Chamberlain, in reply, said that day's proceedings marked a stage in the history of the College. He did not dwell upon the service rendered by the College to the city and

district, its rapid growth, and the reputation it had acquired, which was due in large part to the capacity and the character of the teachers it had been able to attract. The Mason College at the present time was hampered by a lack of resources. They had not the funds to deal with the growing requirements of the time and of the district, to provide proper appliances, proper buildings, and proper remuneration for those who acted as professors and demonstrators in the institution. The Lord Mayor had been good enough to say that the deficit was a moderate one, but deficits had a most uncomfortable habit of increasing, and, although the endowment which was provided for the College by the munificence of Sir Josiah Mason was sufficient for it in its infancy, it was inadequate for present requirements. The trustees had always contemplated the possibility that they would be able to crown the edifice of their educational institution by the establishment of a local University to meet the requirements of the district, and he need hardly point out that if that object found favour in their eyes, as the greater included the less, so the relief desired would come in the creation of a properly-endowed University into which the Mason College would be practically absorbed. He hoped the ambition to which he had referred would not in the present day be considered unreasonable.

THE MULTIPLICATION OF UNIVERSITIES.

There was a time, no doubt, when members of the older Universities, and men who were altogether independent of them, believed that the multiplication of Universities would injure education; that it would lead, in a certain sense, to the degradation and the lowering of the value of the degrees which Universities conferred; but very much had happened in the last twenty years, and he could hardly imagine any reasonable man arguing in that strain at the present moment. The fact was the need of the local University had been recognised, and at the present time Birmingham, and the surrounding district, was the only great centre in England which was not already provided with such an educational institution. Liverpool, Manchester, and Leeds had their Victoria University; Newcastle was closely connected with Durham; Wales had its own University; London had a University of a kind, which, when Londoners were able to make up their minds, would no doubt develop into something much better. He could not conceive of any district at the present time which more needed or more deserved the establishment of such an institution than the district in which he was speaking. But if they went outside England the argument was greatly strengthened. They looked to Germany for an example and a model of everything in the way of educational organisation and progress. Education was made in Germany, and they were not ashamed to take the lesson to heart. Germany, with forty-six millions of people, had twenty-one Universities. Their own sister kingdom, Scotland, with four million people, had four Universities; in England and Wales, with nearly thirty millions of people, they had six Universities. *A priori*, at any rate, he thought they had made out a case for a University.

EDUCATION IN THE MIDLANDS.

But there were other reasons he drew from the educational history of the district. The right hon. gentleman then proceeded to sketch the rapid and remarkable development of education in the district, speaking in high terms of the educational institutions. They had Mason College, which at last had been incorporated as a full University college. Was it not clear that after that which had been accomplished so rapidly they might ask without presumption for an institution which should crown that circle of their educational opportunities, and which should direct and control and guide and coordinate these local educational works, and so put themselves in a position to equal and rival every other part of the kingdom? He would like to strengthen his argument by a quotation from a man who, perhaps more than any other, was qualified to speak upon that subject—he meant the late Prof. Huxley, who said: "But a city University is, in my judgment, a corporation which has charge of the interests of knowledge as such, and the business of which is to represent knowledge by the acquirement by its members of increased knowledge, by their investigations to diffuse knowledge, by their teaching, and last, but not least, to create a respect for knowledge among their fellow men by their personal example and influence." Prof. Huxley was writing then in reference to the proposed creation of a University for Manchester. Whatever argument was then applicable to Manchester was applicable in no less a degree to Birmingham and the district, because he believed that there was no district in the kingdom that was so distinct in what he might call the peculiar genus, knowledge, and character of its people, and in the nature of its occupations as that great manufacturing district which had the vast population of more than 2,000,000 or so in and around Birmingham within a radius of twenty or thirty miles.

THE OBJECTS OF THE UNIVERSITY.

What did they mean by a University? What new institution was it they desired to place in Birmingham? They meant, he took it, a great school of universal instruction not confined to any particular branch of knowledge, but taking all knowledge as its province, and arranging regular courses of complete instruction in all the great branches of information. They must, in the second place, use that knowledge so that the professors and teachers should be associated with the students, and all should be students together, and so that those who came to teach should continue to learn, and so that the most important work of original research should be continuously carried on under the most favourable circumstances; and, lastly, they meant by a University a body which should have power to control the courses of education and to confer degrees which should test the value of its instruction. He put that last because he believed that of the three objects of the University it was the least important, although it was necessary to a University, and without it Mason College had lost a number of students. One thing he might at once admit. Any new University which they might succeed in establishing would not be in any sense a competitor with the old Universities of Oxford and Cambridge. Those Universities appealed necessarily to classes many of whom they could not expect to touch, and they offered associations, traditions, and conditions which they could not under any circumstances attempt or hope to emulate. Therefore, while they could not imitate Oxford and Cambridge if they would, he would say also that they would not if they could, because, while the older Universities supplied a want of their own, and if anything were to happen to them they would leave an incalculable gap in all that was interesting and picturesque in English life and English history, yet when they came to create new Universities in this modern time and under modern conditions it was something rather different that they had in view. He would say, rather, that they should take as their model, not indeed absolutely, the great Universities of Scotland—of Edinburgh or of Glasgow. He thought the University of Glasgow was built, much as they hoped theirs would be, upon a pre-existent college which had subsequently been absorbed or developed into a University. But there was no doubt whatever, from the experience of such Universities as those he had referred to, that to place them in the middle of a great industrial and manufacturing population was to do something to elevate the whole mass to higher aims and higher intellectual ambitions than would otherwise be possible to people engaged entirely in trading and commercial pursuits.

THE NEED OF MONEY.

Rome was not built in a day, and their University would, he dare say, for generations yet to come give opportunities to liberal benefactors to improve and extend it. But one thing was essential, one thing they must do—put the University in a position to attract the best teachers, to attract men of the highest reputation, and to keep them there when they had induced them to come. Pointing out how this ideal could be attained, Mr. Chamberlain remarked that all they wanted was very little—only money; and that, he hoped, would be forthcoming. The sacrifice must be proportioned to the importance of the object they had in view. He had no idea that Birmingham or the district would be satisfied with a starved University. He would rather wait another fifty years if necessary than start with everything pinched and mean about them, with insufficient buildings, with inadequate appliances, and, above all, with insufficient remuneration for those whom they employed. Therefore, he urged that they should start the scheme with a determination to make it a great success. Let them start it with an endowment which, at all events, would secure the main objects which they had in view. It was calculated that what would be required would be 250,000*l*. He was not at all inclined to minimise a demand of that sort made under the circumstances. Money would not be spent in colossal buildings. They must come later on. It was chiefly to secure a satisfactory endowment for a complete professorial body in connection with the University. In addition to the chairs which were already endowed they wanted endowments varying from 400*l.* to 600*l.* a year, which he did not think would be considered by any one as excessive, for fifteen chairs. The cost of such an endowment was, therefore, from 12,000*l.* to 20,000*l.* If this work was to be carried on they must not expect too much from individuals. They might expect something from the great trade of Birmingham, a little from each member of the trade, if they would organise themselves for the purpose. The great industries when appealed to would see that they had a great duty in that matter, and would be glad to be represented in the work. They had already made some progress, and from two or three whom they had approached they might certainly expect the endowment of such a professorship. His duty that day was to put the question before them and ask them to accept the principle and give their good will and assistance in carrying it out.

FRANCESCO BRIOSCHI

BIOGRAPHICAL notices of this veteran Italian mathematician, who died on December 13 last, have been given in the *Comptes rendus* by M. Hermite, and by Cremona and Beltrami in the *Annali di Matematica*, the journal of which Brioschi was chief editor, and one of the founders in 1858; from these notices many of the following details of Brioschi's scientific work have been extracted.

This work covers about half a century in time of production, and ranges over the subjects of Analysis, Geometry, Higher Algebra, Differential Equations, Elliptic and Abelian Functions, Mechanics and Mathematical Physics.

Brioschi occupied himself at first with various dynamical questions, in continuation of the researches of Lagrange and Dirichlet. He next turned to the development of Gauss's analytic theory of surfaces, which had hitherto not attracted the attention it deserved. He also discussed the theory of the Correspondence of Poncelet's Polygons; as subsequently developed by Moutard and Halphen, this theory appears likely to provide the simplest analytical view of the Multiplication and Division of Elliptic Functions, at present engaging the attention of Prof. H. Weber.

But the true bent of Brioschi's genius was found when he attacked the general theory of algebraical equations, being inspired by Hermite's discovery of the transcendental solution of the quintic equation, which has recently been summarised with developments in Klein's Lectures on the "Ikosahedron."

The history of the quintic equation throws a curious light upon the ways of a certain typical British school of mathematicians, who are accustomed to jog along in intellectual isolation, knowing and caring nothing for the advances made by others; like "Rip van Winkles," as Clifford called them.

Working in this hermit-like way, Mr. Jerrard made the important discovery that it was possible by the solution of algebraical equations of an order not higher than the third, to reduce the general quintic equation to the trinomial form; but Klein has pointed out, in the "Ikosahedron," that all this had been done a hundred years ago, by the Swedish mathematician Bring, in 1786.

Arguing by analogy, Mr. Jerrard, it is related, was firmly convinced that by the solution of a quartic, it would be possible to reduce the quintic to the binomial form, when the algebraical solution would be complete; and he died in happiness before having discovered his error, which a slight acquaintance with the work of Abel and Galois would have revealed.

The reduction by Hermite of the general quintic equation to the form of the Modular Equation of the Transformation of the Fifth Order of Elliptic Functions suggested to Brioschi the examination of the corresponding equations of higher order; and Brioschi's last communication was one to the Mathematical Congress at Zürich, 1897, on the particular case of the Transformation of the Eleventh Order.

Galois's statements ("Les idées précipitamment émises," Halphen, "Fonctions elliptiques," iii. p. 124), which he did not live to demonstrate, that the Modular Equations of the Fifth, Seventh, and Eleventh Order have Resolvents of the same order, had long baffled analysts, and they did not receive universal acceptance till the appearance of the article in "Tortolini," 1853, by Betti, Brioschi's co-editor, who succeeded in retracing Galois's line of argument; Betti's article being followed up by Hermite, in the *Comptes rendus*, 1859.

In his biographical memoir M. Hermite points out that Brioschi was the pioneer in another line of generalisation in the theory of algebraical equations, in his discovery of the solution of the general sextic equation, employing for that purpose the six even Θ functions, of two variables. The details of the development of this theory will afford plenty of employment to young mathematicians for some time to come.

In addition to his scientific labours, Brioschi found time to devote to public duties; he acted as an Under-Secretary of State, and was a Senator of the Upper House of the Italian Parliament; he was an organiser of the railway system of Italy, and he served on the International Committee of the Metric System.

He was a member of most of the Academies and Scientific Societies of Europe and America, and President of the Royal Academy of Lincei. The biographical notices by those who were personally acquainted with him speak highly of the respect and esteem which he inspired.

G.

REV. C. L. DODGSON.

A FORMIDABLE champion of Euclidean methods in the elementary teaching of geometry has just passed away after a short illness. The Rev. Charles Lutwidge Dodgson was born in 1832 at Daresbury in Cheshire; and, after passing five years at Rugby School, matriculated in 1850 at Christ Church, Oxford, where he was appointed a student in 1852, and graduated in 1854 with honours in both classics and mathematics. He was appointed Mathematical Lecturer in the College in 1855, and retained that office till 1881; he further served the University as Mathematical Examiner in 1863, and Moderator in 1868.

The mathematical subject in which he was most interested was the elementary teaching of geometry; of this he had a personal experience of twenty-six years. Without stint of labour he submitted to rigid logical analysis every text-book on the subject that came to his notice, undismayed by their surprising number, the result being the amusing and, at the same time, deep "Euclid and his Modern Rivals," published in 1879, in which he demonstrated the logical superiority of Euclid's method over all the others examined. The Appendices of this book are very valuable. A "Supplement" to it appeared in 1885. In 1882 he edited Euclid, Books I. and II., with an introduction; and in 1888 he published "A New Theory of Parallels," in the third edition of which (1890) he simplified his fundamental axiom.

His other mathematical work comprises "A Syllabus of Plane Analytical Geometry" (1860), "Formulæ of Plain Trigonometry" (1861), "An Elementary Treatise on Determinants" (1867), "Euclid, Book V., proved Algebraically" (1874), and "Pillow Problems" (1893). He invented a new method of evaluating determinants, which is published in the *Proceedings* of the Royal Society for 1866, and also a method (which was published in NATURE) of easily determining the day of the week corresponding to any date. In October last he described in Nature a brief method of dividing a given number by 9 or 11; and a second paper on the same subject, which appears in our correspondence columns this week, probably represents his latest contribution to mathematics.

A characteristic of all his work was the absolute exactness of expression at which he aimed, so that his definitions and proofs should be logically perfect. This carried a certain severity into his work, since, as he has himself remarked, a semi-colloquial style is apt to be also semi-logical, as nothing is more easy than to forget, in an argument which is interwoven with illustrative matter, what has, and what has not, been proved. It further tended to require the repetition of what might for exactness have to be a somewhat cumbrous periphrasis, to prevent which, therefore, he introduced a number of new terms and symbols; few of these have, however, been adopted into general use, though of the latter some are extremely expressive, and in his hands were of great value.

Mr. Dodgson's mind was essentially logical, in spite of the whimsical humour which has endeared "Lewis Carroll" to every boy and girl—nay, every adult—in the kingdom; and of late years he devoted a large part of his time to the study of the syllogistic methods of formal logic. In 1887 he published "The Game of Logic," and in 1896 "Symbolic Logic, Part I."

A shy and retiring man, he was to his friends a most charming companion, overflowing with the quaintest of humour, and one whose love for children was typical of himself, and whom to know was to love.

NOTES.

Mathematicians of all countries will be glad to hear that active steps are being taken to perpetuate the memory of the late Prof. J. J. Sylvester in a manner worthy of his reputation and in consonance with the spirit of his work. The movement was originated in this country by a few friends and admirers of the late Professor's, who decided upon founding a Sylvester Medal for the encouragement of mathematical research. The sympathy with the movement displayed by all the mathematicians who were communicated with, led the initiators to the conclusion that the most appropriate memorial would be one of international foundation, the more especially as Sylvester had a large number of friends and pupils in America, where indeed he may be said to have brought about a mathematical awakening through his connection with the Johns Hopkins University. The list of the International Committee which has now been issued, although only a preliminary one, comprises nearly the whole of the leading mathematicians of the world, besides many of the personal friends of the deceased mathematician and the representatives of the Universities of Oxford, Cambridge, London, Glasgow, Edinburgh and Dublin. From this list it might appear invidious to select names, but it is satisfactory to be able to call attention to the fact that it includes the Chancellor, High Steward and Counsel of the University of Cambridge, the Vice-Chancellor of the University of Oxford, the Provost of Trinity College, Dublin, the President of University College, London; with Lord Kelvin and Prof. P. G. Tait as representatives of the Universities of Glasgow and Edinburgh, and Prof. Henrici of the City and Guilds Institute. France is represented by Profs. Hermite, Poincaré, Camille Jordan, and Darboux; Germany by Profs. Schwarz, Klein, Fuchs, Gordan, and Lindemann; Italy by the late Prof. Brioschi, and by Prof. Cremona; and Sweden by Prof. Mittag-Leffler. America has no less than fifteen names on the list, among them being President Gilman of the Johns Hopkins, Profs. Simon Newcomb, Willard Gibbs, and others representing the mathematical chairs of the various Universities. It is indeed certain that some movement of the kind would have been initiated in America if Sylvester's admirers in this country had not taken action. Now through Dr. Cyrus Adler, of the Smithsonian Institution, and Dr. G. Bruce Halsted, of Texas (a former pupil of Sylvester's), the Americans are working for the general scheme, and the two gentlemen named are acting as Treasurers for the United States. The general Treasurer of the fund is Lord Rothschild; Major P. A. MacMahon is acting as Hon Secretary, and Prof. Meldola, as a friend of the late Prof. Sylvester's, undertook the arduous work of preliminary organisation with the results which we are now making public. The executive Committee consists of Lord Rothschild, Major MacMahon, Prof. Forsyth, Prof. Greenhill, Prof. Henrici, and Prof. Meldola as Organising Secretary. We are informed that the subscriptions from private sources reached over 500*l*. at the end of the year, and now exceed 600*l*., the American contributions not having yet been forwarded. It is proposed that the Medal shall be awarded triennially through the Council of the Royal Society, irrespective of nationality. Any friends of Sylvester's, or others who desire to participate in the movement, may send contributions to Lord Rothschild, New Court, St. Swithin's Lane, E.C.

Mrs. Tyndall, the widow of Prof. Tyndall, has sent the following letter to Sir James Crichton-Browne, F.R.S., the Treasurer of the Royal Institution: "Dear Sir James,—As an expression of his attachment to the Institution, with which he was so long connected, and of his sympathy with its objects, my dear husband desired me (at such time as should be most convenient to myself) to present in his name to the Royal Institution 1000*l*. to be disposed of as the Board of Managers may see fit for the promotion of science. I have now the pleasure of remitting to you this sum. Yours faithfully, Louisa C. Tyndall." Sir James Crichton-Browne, in the course of his letter acknowledging this generous donation, remarks:—"The managers would, I am sure, desire to be guided by any wish of yours as to the application of the gift; but, in the absence of any explicit directions, they will, I have no doubt, employ it in the promotion of that original scientific research in which your husband's vivid and penetrating intellect delighted to exercise itself. Revered as your late husband's memory is, and ever must be, in the Royal Institution, this posthumous mark of his solicitude for its welfare will, if possible, deepen the affectionate esteem in which he is held."

The Council of the Royal Astronomical Society have awarded the Gold Medal of the Society for this year to Mr. W. F. Denning, "for his meteoric observations, his cometary discoveries, and other astronomical work." The award was confirmed on Friday last, and the medal will be given at the annual general meeting next month.

The deaths are announced of Dr. Eduard Lindemann, scientific secretary in the observatory of Pulkova; and Dr. Oscar Stumpe, well known for his contributions on the motion of the solar system.

Dr. Maquenne, assistant at the Paris Muséum d'histoire naturelle, has been nominated professor of plant physiology, in succession to the late M. Georges Ville.

At the February meeting of the Edinburgh Mathematical Society, a discussion on the proposal that, in the teaching of elementary geometry, Euclid's definition of proportion be abandoned, will be introduced by Prof. Gibson.

We regret to see the announcement of the death of Lieut.-Colonel C. Cooper-King, lecturer in natural science at the Staff College, Camberley. Colonel Cooper-King was a Royal Marine Artillery officer, and before joining the Staff College was an instructor at the Royal Military College, Sandhurst.

A LETTER which appears in our correspondence columns, on poisoning from Koda millet, which is extensively used as a food-grain in times of scarcity, furnishes another instance of the urgent need that exists for further facilities for scientific investigation in India. Matters are continually arising which ought to be made the subjects of systematic inquiry, but at present the means for carrying out such investigations are altogether inadequate to the wants of our great Indian Empire.

WE learn from *Science* that ground was formally broken for the Museum Building of the New York Botanical Garden on December 31. The construction and equipment of the building will cost 347,019 dollars. The plans for the great range of horticultural houses have been completed, and specifications for them have been printed. The sum of 15,000 dollars, in addition to the funds provided by the Act of Incorporation, has been made available for the building of portions of the drive-way system. During the past season about 2900 species of plants have been obtained, together with large quantities of museum, library, and herbarium material.

THE Royal Photographic Society is organising an international exhibition of photographic apparatus and photographs, which will open at the Crystal Palace on April 27. In addition to the usual displays of pictures, &c., the leading firms, manufacturers and dealers, will be largely represented. There will also be extensive loan collections, illustrating not only the history of photography, but its scientific and commercial applications, photo-mechanical processes, photographs in colours, photographs by means of the X-rays, and kindred exhibits. The exhibition, the arrangements for which are in the hands of a joint committee of members of the Society and exhibitors, promises to be the largest and most interesting collection dealing with photography that has ever been got together.

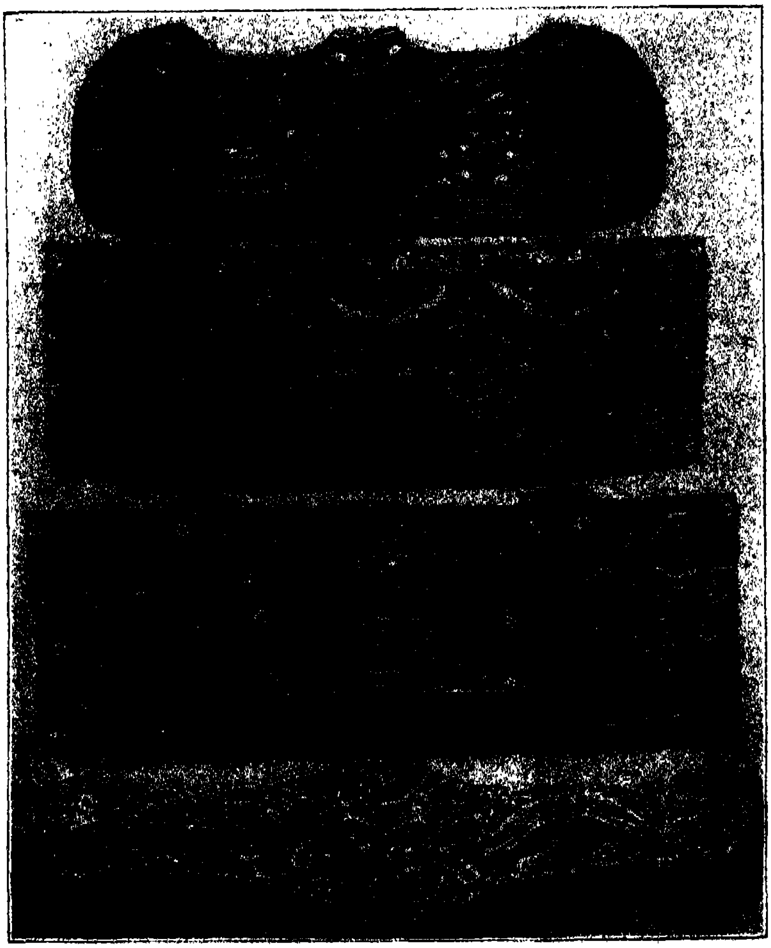
THE sixteenth annual meeting of the American Society of Naturalists and Affiliated Societies was held at Cornell University at the end of last year. In the absence of the president, Prof. Whitman, of the University of Chicago, the chair was taken at the opening meeting by Prof. S. F. Clarke. The officers elected for the ensuing year are:—President: H. P. Bowditch, Harvard Medical School. Vice-Presidents: Prof. Wm. James, Harvard University; Prof. Simeon H. Gage, Cornell University; Prof. H. S. Williams, Yale University. Secretary: Prof. H. C. Bumpus, Brown University. Treasurer: Prof. John B. Smith, Rutgers College. Executive Committee: Prof. J. P. McMurrich, University of Michigan; Prof. E. G. Conklin, University of Pennsylvania. At the instance of Prof. Morgan, of Bryn Mawr College, the Society voted one hundred dollars towards an additional table at the Naples Marine Biological Station, and fifty dollars for the Naturalists' Table at Woods Holl. It was reported that President McKinley was about to appoint a politician to the office of Fish Commissioner, and the sentiment of the assembled investigators upon this matter is shown in the following resolution presented by Prof. C. L. Bristol, of New York University, and supported by Prof. H. F. Osborn. "Resolved: (*a*) That the American Society of Naturalists as representatives of the principal scientific and educational interests of this country, unanimously express to the President and Congress of the United States their sentiments that the Commissioner of Fish and Fisheries should, according to the law of 1888, governing his appointment, be a person of proved scientific and practical acquaintance with the fish and fisheries of the coast. (*b*) That it is of the utmost importance that the Fish Commission, as one of the most useful scientific institutions of the Government, should be free from political influence and should be administered with the highest degree of scientific efficiency by an experienced officer." A discussion was held on the subject of "The Biological Problems of To-day," and it was dealt with from the points of view of palæontology, botany, anatomy, psychology, physiology, developmental mechanics, and morphogenesis. In addition to the combined meetings of the societies, the following bodies held separate meetings for the communication and discussion of papers bearing upon their particular branches of science: American Physiological Society, American Morphological Society, American Psychological Association, Association of American Anatomists, Association for Botanical Morphology and Physiology, Section of Anthropology of the American Association. The Society will meet next winter at New York.

IN the *Zeitschrift für Vermessungswesen*, Prof. Hammer directs attention to a Babylonian plan depicted on a clay tablet found in the excavations at Tello, and now preserved in the Constantinople Museum. The plan was made about 3000 years before the Christian era, and represents an estate belonging to King Dungi. It is of importance not only as a contribution to the early history of surveying, but also as a confirmation of the views on Babylonian measures of length and of area propounded by Reisner at a meeting of the Berlin Academy of Sciences on April 9, 1896. A copy of the plan has been examined by Eisenlohr, the eminent authority on Egyptian archæology, and he claims to be able to read from the cuneiform inscription the names of the two surveyors engaged. On one side of the tablet there is a dimensioned sketch of the plan of the estate not drawn to scale. The estate is divided by the survey lines into rectangles, right-angled triangles, and trapeziums. In each case the area is stated, two results obtained by different methods being given. Eisenlohr has plotted the survey, and his calculations of the area agree with the results given on the tablet. On the other side of the tablet the areas of the various portions are added together, two sets of figures being used, and the arithmetical mean taken as the correct area. The unit adopted, the *gan*, is thought to be equal to 4199 square metres. The absolute measures are, however, of slight importance. More important is the fact that land surveying was carried on 4000 years B.C., apparently in an accurate manner, and certainly with check measurements.

M. E. DUBOIS (*Bulletins de la Société d'Anthropologie de Paris*, 1897, fascicule 4) infers from theoretical grounds, based partially upon observation of the proportion of the surface of the retina to that of the body, that the weight of the brain of mammalia of similar form and the same species, varies directly as the surface of the animal.

A FRESH development of Dr. Folgheraiter's investigations on the magnetic properties of Etruscan vases is described in the *Rendiconti della R. Accademia dei Lincei*, vi. 12, the object of the present experiments being to discover by what process the black vases obtained their colour. Three hypotheses had been advanced by archæologists: the first, that the vases were made of a special kind of clay; the second, that the clay was mixed with fine carbon or lamp-black; and the third, that the colouring matter was introduced into the clay after the vases had been formed, and possibly after they had been baked. Dr. Folgheraiter found, however, that carbon mixed with clay disappeared almost completely when heated to a temperature of about 380°, and that fragments of the old vases also lost their colour at that temperature; while to account for the magnetic properties of the vases they must have been heated to over 420°. Moreover, the clays experimented on did not lose their plasticity until a temperature of 420° to 500° was reached. The first two hypotheses were thus negatived. With regard to the third, it was found that the blackening could not be effected by heating in a closed chamber full of carbon; moreover, if the carbon was infiltrated into the pores of the clay by carbonisation, it did not burn away till a higher temperature was obtained than was sufficient to decolorise the vases. Thus neither of the three hypotheses was corroborated by experiment. Dr. Folgheraiter suggests as a possible explanation that the clay, after being baked, may have been soaked with bitumen, and then heated to 300°; it would thus acquire a polished black surface with the colour gradually fading towards the interior, as in these Etruscan vases.

THE "Illustrations of Maori Art," by Mr. H. Hamilton, now in course of publication by the New Zealand Institute, is the most attractive contribution to ethnography we have seen for a long time. The first part of the work, on the Canoes, was issued some months ago, and the second part, dealing with material relating to "Maori Habitations," has lately come to hand. The three succeeding parts will be devoted to weapons, dress and decoration, and social life. The present part contains twenty-three plates upon which are reproduced, by half-tone process, photographs of characteristic buildings of the New Zealanders, and ornamentations with which the framework and different parts of the habitations were embellished. The accompanying illustration, which reproduces one of the plates on a reduced scale, is a testimony to the ability of the Maoris as wood-carvers, and to the high quality of the pictorial part of Mr. Hamilton's work. The carvings here shown are ornaments for doorways, the three upper ones being in the South Auckland Museum, and the lower one in Mr. Hamilton's own collection. In addition to illustrations of this kind there are twenty-nine examples, in chromo-lithography, of Maori rafter patterns; diagrams of the construction of a Maori house; a valuable introduction on the habitations of the Maoris; and descriptive notes on the illustrations. The work is commendable both in plan and execution, and when it is completed we shall refer more fully to its scope and value.



Maori Carvings for Doorways.

A PHOTOGRAPHIC method of measuring the height of a balloon, and at the same time comparing the results with those furnished by barometric readings, is described in *La Nature* for January, by M. L. Cailletet. The apparatus consists of a camera with one lens pointing downwards, by means of which a photograph of the country below the balloon is taken; at the same time a lens at the top of the camera projects on the upper side of the sensitised film an image of the dial of an aneroid barometer placed above the apparatus. By measuring the distance between any two points on the photographic view, and comparing with a map of the district, the altitude of the balloon can be accurately found, and the law connecting it with the barometer reading verified experimentally.

THE Pilot Chart of the North Atlantic Ocean, issued for the present month by the Hydrographer of the United States, shows that some very severe weather was experienced during December. Many of the storm centres were in high latitudes, so that vessels along the Transatlantic routes met with north-westerly squalls of hurricane force, accompanied with snow and hail. The most severe storm of the month was one situated about latitude 54° N., longitude 44° W., on December 6, and which reached the neighbourhood of the Orkney Isles on the 8th and 9th. For some days the wind blew with hurricane force north of latitude 55° N., and east of longitude 20° W. It often happens, especially in the winter season, that in the vicinity of the Azores rough weather is experienced or several days at a time; and, with the view of illustrating the behaviour of these storms, a synoptic chart of one of them is given. They differ from the storms of other regions in that the barometric depression rarely attains any great depth, and that they follow an irregular course, the centre frequently recurving in a manner suggesting an effort to get to the eastward in the face of some resisting force, probably an area of high barometric pressure in the vicinity of the British Islands. Another feature of these storms is the suppression of the trade-winds, which is an important consideration for vessels bound from the Equator to the Channel.

DR. A. FRANZ contributes a long paper to the *Deutsche geographische Blätter*, on the possibility of establishing regular communication by sea between Europe and Western Siberia. The meteorological and hydrographical conditions are examined with as much detail as the somewhat scanty observations available admit; and the general result seems to show that the difficulties in the way of regular navigation are not insuperable, although sufficiently great to make it doubtful if it is worth while, from a commercial point of view, to try to overcome them.

THE first part of a new volume of the *Memorie della Società Geografica Italiana*, recently issued, contains, besides other shorter papers, the results of an exhaustive research into the records of earthquakes in Italy during the period 1800 to 1872, by Signor M. Baratta. The author does not pretend to completeness, but his list is, as he says, a great advance on anything hitherto available. The arrangement is chronological, and under each date are given the places where the disturbance was recorded, the hour, the nature, direction, and intensity of the shock when possible, and finally the source of information.

THE *Mittheilungen du k.k. Geographischen Gesellschaft* of Vienna contain a note announcing satisfactory progress in the work of organising a meteorological service in the parts of the Balkan peninsula under Austrian rule. Discussion of the observations already made throws considerable light on the obscure transitional phases of climate occurring between the Mediterranean and continental regions.

WE have received the third volume—that for 1894—of the *Bibliotheca Geographica*, edited by Dr. Otto Baschin. The work has been carried out with the same completeness and accuracy as formerly. The only new feature is an extension of the number of Slavonic languages included. The experiment of giving titles of papers in Russian and Czech, with German translations appended, was tried for the first time last year, and has been so far successful that Polish and Croatian literature is now added.

THE Director of the Botanic Gardens at Buitenzorg, Java, has issued in English a Hand-guide to the Gardens, in a neat square size, accompanied by a plan.

WE have received from the Gebrüder Borntraeger of Berlin a daintily produced catalogue of their natural history publications, especially in botany and geology. The firm has now been in existence over a century.

IN the *Transactions of the Academy of Science of St. Louis*, Prof. W. Trelease describes a remarkable instance of "phytobezoar," two balls from 3 to 4 inches in diameter, taken from the stomach of a bull, and composed entirely of the barbed hairs with which the cushions of species of *Platopuntia* are covered.

WE learn from the *Botanical Gazette* that the Secretary of Agriculture for the United States has included in his estimate of the expenditure for the coming year an item of 20,000 dols., to be set aside from the seed fund, for the introduction into the States of valuable economic plants. If sanctioned by Congress, Mr. D. G. Fairchild will be put in charge of the work. His extensive travels and his reputation as a botanist peculiarly fit him for the work.

THE *Botanical Gazette* states that the Biological Survey of the State of Alabama is being pushed and extended as rapidly as limited means will permit. Over 20,000 specimens have been added to the herbarium collection during the present year, including fine series of lichens, mosses, and liver-worts. Much of the success of the work is due to the activity and devotion of Prof. F. S. Earle and Mr. Carl F. Baker, of the Alabama Polytechnic Institute, and of other botanists of the Survey.

THE pitcher-plants of the genus *Nepenthes* are just now engaging the attention of systematic botanists. In the *Journal of the Royal Horticultural Society* for December 1897 is an elaborate article on their growth and culture by Mr. H. J. Veitch, with numerous excellent illustrations, to which are appended some remarks by Mr. F. W. Burbidge. Mr. F. M. Bailey describes the four Australian species in the *Queensland Agricultural Journal*, vol. i. part 5, giving figures of two of them.

THE first number of the new volume (vol. ix.) of the *Journal of Conchology* contains articles and notes of interest to conchologists. The size of the page has been enlarged, and an index is given of the volume just completed. Among the contents is the presidential address delivered by Prof. S. J. Hickson, F.R.S., on "Torsion in Mollusca." Mr. Lionel E. Adams records observations which distinctly show that the slug *Limax maximus* has a sense of smell.

THE eighth part of Mr. Oswin A. J. Lee's attractive work, "Among British Birds in their Nesting Haunts," has just been published by Mr. David Douglas, Edinburgh. The nests illustrated upon the ten fine plates are those of the song thrush, great crested grebe, great skua, tawny owl, bearded tit, common curlew, and siskin. This part appears to conclude the second volume of Mr. Lee's work.

A GOOD general view of physical and chemical science, designed mainly for medical students, is given in the "Physikalisch-chemische Propaedeutik" of Prof. Dr. H. Griesbach. (Leipzig: Engelmann.) The book is being published in parts, and the second part of the second half has just appeared. A knowledge of the principles of physics and chemistry is essential to the student of modern medicine, and Dr. Griesbach has set himself to show how physical methods bear upon medical science. Another part of the work remains to be published, and when it appears, we shall review the book in its completed form.

THE simplest member of the group of the ketoses, of which ordinary lævulose or fruit sugar is the best known representative, is dihydroxyacetone, $CH_2(OH).CO.CH_2(OH)$, which has long eluded the attempts of chemists to isolate it in the pure state, although mixtures in which it is undoubtedly present have been obtained by several investigators by the oxidation of glycerine. Oscar Piloty has now succeeded in preparing this interesting compound in the pure condition, and describes its properties in the current number of the *Berichte*. The starting point for its preparation is the oxime, $CH_2(OH).C : NOH.CH_2(OH)$, which can easily be obtained from the product of the action of formaldehyde on nitromethane, both substances of very simple constitution. When this oxime is treated with bromine, nitrous oxide is evolved and dihydroxyacetone produced. It crystallises well, and has a sweet and cooling taste. In other respects it also shows the well-known characteristics of the sugars, reducing Fehling's solution almost as powerfully as grape sugar, and yielding an osazone with phenylhydrazine. On reduction it is converted into glycerine, a new synthesis of this important compound being thus effected. The production of dihydroxyacetone from formaldehyde is of great interest in view of the important function which the latter is supposed by many to perform in the natural production of sugars in the vegetable organism.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. R. S. Gleave; two Aard Wolves (*Proteles cristatus*, young) from South Africa, presented by Captain Baker; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, presented by Lady Pilkington; a Black-backed Piping Crow (*Gymnorhina tibicien*) from Australia, presented by Mr. T. G. F. Winser; two Herring Gulls (*Larus argentatus*), British, presented by the Rev. F. Hopkins; a Japanese Ape (*Macacus speciosus*) from Japan, two Ganga Cockatoos (*Callocephalon galeatum*) from Australia, a Red-tailed Buzzard (*Buteo borealis*) from Jamaica, deposited.

OUR ASTRONOMICAL COLUMN.

A NEW SPECTROSCOPIC BINARY.—In the Harvard College Observatory *Circular* (No. 21) Prof. E. C. Pickering announces that, from an examination of the Draper Memorial photographs, Mrs. Fleming has found that the star A. G. C. 20263, β Lupi, is a spectroscopic binary. The period has not yet been determined, but photographs are being taken for this purpose.

Measures of the spectroscopic binaries μ^1 Scorpii and A. G. C. 10534 show that the relative velocities of the components are approximately 290 and 380 miles respectively. The velocities are therefore much greater than in the case of ζ Ursæ Majoris and β Aurigæ. The separation of some of the lines amounts to as much as nine tenth-metres.

WINNECKE'S PERIODIC COMET.—A short time ago (NATURE, December 23, 1897) we gave Hillebrand's search ephemeris for this comet, and subsequently (January 6, 1898) announced its discovery by Perrine at the Lick Observatory, with a slightly different position from that calculated.

A supplementary note in the *Astronomical Journal* (No. 423) gives the corrections to be made to Hillebrand's ephemeris as

$$\Delta\alpha = +\ 2\text{m. } 8\text{s.},\ \Delta\delta = -\ 9'\cdot3.$$

Applying these values, we have the following approximately corrected ephemeris.

Berlin M.T.		α h.	m.	s.		δ °	′
1898, Jan. 18·5	...	16	22	8	...	− 7	51·4
„ 22·5	...	16	39	7	...	− 8	46·3
„ 26·5	...	16	54	44	...	− 9	39·6
„ 30·5	...	17	14	57	...	−10	30·6

LEVEL OF SUN-SPOTS.—Much has been said on both sides of the question as to whether sun-spots are concave or convex; and although the Wilsonian doctrine is generally accepted, there are at the same time many difficulties which tell against it.

At first sight it would seem that notches, seen and photographed when a spot is on the limb, go to support the theory; but on the contrary, as Father Sidgreaves pointed out (*Monthly Notices*, vol. lv. p. 285, 1895), they are difficult to account for by it. Again, a more serious objection than this is that both Langley and Frost have found that the ratio of umbral radiation to that of the neighbouring photosphere undoubtedly increases with the distance from the centre of the sun's disc; from this result it would seem that the umbral region whose radiation was measured was above the level of the photosphere, and consequently subjected to less absorption.

In the *Astrophysical Journal* (vol. vi. p. 366), Prof. George E. Hale considers the conclusions which seem to be at variance with the idea that spots are depressions, and suggests that spots may be hollows in comparatively small areas of the photosphere which are raised above the ordinary level; for most admit that the penumbra is at a higher level than the umbra, and it cannot be doubted that penumbral filaments overlie the umbra, and frequently unite to form bridges extending completely across it.

This theory, so far as he has examined it, seems to reconcile the conflicting testimony offered by the supporters of the two views. Notches at the sun's limb are accounted for by assuming that the side of the spot nearest us is somewhat lower than the opposite penumbra, and the darkening of the limb might thus be produced by the smaller radiations of the penumbra. Also, to account for the results obtained by Langley and Frost, it is only necessary to assume that the region of the umbra is slightly raised above the general level of the photosphere.

A VARIABLE BRIGHT HYDROGEN LINE.—From a comparison of the Draper Memorial photographs of the star A. G. C. 9181, taken on different dates, Miss A. J. Cannon has found that the bright hydrogen line Hβ is variable (Harvard College Observatory *Circular*, No. 21). On October 5, 1892, it was invisible. On November 28, 1894, it was about half as bright as the corresponding line in A. G. C. 9198, ω Canis Majoris. On April 27 and 30, 1895, the line in A. G. C. 9181 was distinctly the brighter of the two, while in January 1897 it was again invisible. From a large number of photographs of this object taken recently it appears that this line, which was bright in October 1897, is now, December 27, invisible.

ASTRONOMICAL CONSTANTS.—It will be remembered that Dr. Fr. Porro, in a long letter to NATURE (December 9, 1897) on "Astronomical Constants and the Paris Conference," somewhat depreciated the adoption of some of the constants (especially that of precessional motion), believing "that a general renovation of fundamental astronomy must precede a new and authoritative definition of the numbers that the twentieth century must accept as the more probable values." In the *Astronomical Journal* (No. 423) Prof. Lewis Boss gives his rejoinder to Prof. Newcomb's remarks on his first paper, which criticised the adoption of the constant of precessional motion, and regrets that others have not replied before him. The additional note to Dr. Porro's letter referred to above, although very concise, formed to some extent a reply to Prof. Newcomb; but Prof. Boss's second paper goes into the matter in minuter detail. In conclusion, he thinks that the present time seems singularly inopportune for the adoption of a new evaluation of the precessional motion, and suggests that a new and ingoing investigation of the motion of the equinox should be made; for although the investigation made by Newcomb a quarter of a century ago was exhaustive for its time, new evidence has since accumulated which has not been brought to bear upon the problem; and we may confidently look for still more valuable observations from several observatories within the next ten years.

LONGITUDE OF MADRAS.—We have recently received the "Report on the Determination of the Longitude of Madras," by the officers of the Indian Survey. The difference of longitude actually determined on this survey was that between Greenwich and Karachi, the latter place being at the end of the submarine cable of the "Persian Gulf Telegraphs." It was only necessary to commence at Karachi, for the whole area of India has been covered with a network of longitude arcs, and by their means the difference of longitude between Madras and Karachi had been accurately determined beforehand.

The distance from Karachi to Greenwich, extending over 5197 miles of wire, was divided up into four main arcs, viz.:—Karachi—Bushire, Teheran—Bushire, Teheran—Potsdam, Potsdam—Greenwich, the clock comparisons being made by signalling over the telegraph wire connecting these places. The final result of these observations gives the longitude of Madras as 5h. 20m. 59s.·113, with a probable error of ±0s.·0227.

It now rests with the Government of India to decide whether this value should be adopted or not, for a change in the longitude of Madras affects not only British India, but the Malay Peninsula, Tonquin, China, the Dutch Indies, and Australia.

THE ELECTRO-CHEMICAL INDUSTRIES.[1]

TWO months hence there should be celebrated in Como the centenary of Volta's famous discovery, to which we owe the rise of electro-chemistry. Electrical phenomena had been studied long before Volta's time; but if we except the action of the electric spark employed by Cavendish to induce the combination of affinitive gases, no electro-chemical effects had been observed. The analytical power of the voltaic pile was first actually demonstrated by Davy, who made memorable the year 1806 by the electrolytic extraction of potassium from potash. To Faraday, who succeeded Davy, we owe the discovery of the law of electrolytic conduction and the enunciation of the principles of the dynamo. As early as 1842 magneto-electric current generators were employed in the Elkington factories at Birmingham, for electro-plating purposes; and comparatively within recent years the principle of electrotyping has been applied also to copper refining. It is estimated that one-third of all the refined copper required is now produced electrolytically. Metal produced in this way is purer and has a higher conductivity than that produced by the older method, which leaves an admixture of arsenic. The power required is relatively small, and the current density may vary within very considerable limits without detriment to the product and with the gain of great rapidity of deposition. The conditions required are to adapt the strength of the solution to the strength of the current, and when the current density is high to effect a rapid circulation of the electrolyte. Mr. Swan referred to a method devised by himself for producing pure copper wire directly by electrolytic action, so avoiding the slight loss of conductivity due to fusion and drawing. The process, however, was found to be too costly for commercial use.

---

[1] Abstract of the presidential address delivered by Mr. J. W. Swan, F.R.S., before the Institution of Electrical Engineers, January 13.

The electrolytic extraction of metals from their ores is now employed on a large scale, in the case of gold, where it can be profitably applied to the treatment of tailings and waste sludges; of zinc, especially by the recent Hoepfner method of working from the chloride; of aluminium, and of sodium. Aluminium made its first appearance as a commercial product at the Paris Exhibition of 1855. Its price at the time was not far off that of silver. The cost is now equivalent to that of copper, whilst the production has mounted to 2000 tons per annum, and is rapidly increasing. Prof. Richards, well known as the author of the most complete treatise on aluminium, predicts that it is bound to rank next to iron in its production and usefulness to mankind. The principal methods of extraction at the present time are Hall's process, consisting of an electrolytic bath of potassium fluoride, in which alumina produced from bauxite is continuously dissolved; and Heroult's process, in which the solvent consists of cryolite, the double fluoride of aluminium and sodium.

The manufacture of alkali has already undergone many changes the past twenty-five years, one of which is the supersession of the Le Blanc process by the ammonia-soda process of Hemming and Solvay. The electrolytic treatment of brine for the production of soda and chlorine now threatens to displace all the older chemical processes, especially since the introduction of the successful rocking apparatus of Castner and Kellner, in which an end-to-end flow of mercury through three compartments prevents the mixing of the electrolyte, and effects the separation of the sodium and chlorine. A similar industry is the manufacture of chlorate of potash by electrolysis, in a tank divided by a porous partition, with very thin iridio-platinum anodes and iron kathodes. The electrolyte is usually a solution of chloride of potassium maintained at a temperature of 45° to 50° C. The action of this cell results in the formation at the anode of hypochlorite, which is immediately decomposed, with the formation of chloride and chlorate of potassium. In Switzerland and in Sweden this process is worked with great commercial success by the aid of power derived from water.

Amongst the class of electro-chemical processes depending on dissociation and combination at extremely high temperatures, Mr. Swan referred to the manufacture of phosphorus and of carborundum in the Acheson furnace. To the same category belongs the production of calcium carbide and a number of analogous products obtained by Moissan. Calcium carbide, for the production of acetylene gas, is now being manufactured at the rate of 20,000 tons per annum.

The production of ozone, with its secondary derivatives, vanillin and heliotropine, is dependent on another variety of electrical action, in which intermittent or alternating currents of high tension are employed. By the Andreoli and other practical processes, ozone is now being commercially produced and applied to numerous industries, such as the oxidation of oils, the seasoning of linoleum, and the purification of brewers' casks.

Such are a few of the principal uses to which Volta's discovery of the galvanic current is being applied. It remains to be seen how far the electrolytic and other electrical processes will supplant the older chemical processes as time goes on. We are probably at present only on the edge of the field that remains to be explored. Mr. Swan's advice to the numerous young electricians who are setting out in life, is that some of them should turn their eyes towards the rich possibilities that await them in this direction. We often hear that the profession of electrical engineering is already crowded. Here at least is a world that still remains to be conquered.

THE BRIGHTON MUNICIPAL SCHOOL OF SCIENCE AND TECHNOLOGY.

THE accompanying illustration shows the external features of the new School of Science and Technology opened at Brighton by the Duchess of Fife a few days ago. The building was designed by Mr. F. J. C. May, the Borough Engineer and Surveyor.

On the ground floor is a large vestibule with mosaic flooring, from which a wide marble staircase leads to the top of the building. A second staircase gives access to the three floors. On each of the floors there is a corridor extending from the front to the back of the building, for a depth of 162 feet, and from these corridors the workshops, class-rooms, lecture theatres, and laboratories open out on each side, with a master's private room for each department. In the basement are situated the boilers and engines for the electric lighting of the building, and for the supply of hot water and steam for the laboratories; here also is a smithy with forges, electrical workshop, carpentering, plumbing, and brickwork and masonry shops, and a dynamo room.

On the ground floor leading from the vestibule are rooms for the Principal, Secretary, Committee, and office; on either side of the corridor are an engineering drawing hall, an engineering workshop, engineering laboratory, metallurgical furnace room, typography shop, and various class-rooms. The workshop is fitted with a Tangye's gas engine, lathes, planing, slotting and drilling machines, &c.

The first floor is devoted mainly to chemistry and physics. The lecture theatres in both departments are fine halls, capable of seating 220 and 120 respectively. The chemical laboratory is fitted for forty-eight students working at one time, and is fully equipped. Besides class and preparation rooms for each department, the accommodation on this floor comprises, among others, rooms for photometry, and advanced physics, chemical research room, balance room, and photographic dark room. The second floor contains a lecture theatre and laboratory for the natural sciences, and lecture and class rooms for dressmaking and cookery.

The day school is a technical college, and provides extended courses in mechanical and electrical engineering, chemistry, natural sciences, and for the Arts and Science degrees of London University. The evening school provides courses in all science subjects, with practical trade classes in building, engineering, printing and chemical trades; languages, commercial subjects, and women's work. The staff of the school is composed as follows:—Principal, C. H. Draper, B.A., D.Sc.; chemistry, M. C. Clutterbuck, B.Sc., Ph.D.; natural science, H. Edmonds, B.Sc.; engineering, G. Armstrong, M.Sc. The total cost of buildings and equipment will be about 25,000*l.*

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. W. Ridgeway has been re-elected Disney Professor of Archæology.

Mr. Yule Oldham, University Lecturer in Geography, lectures this term on the Geography of Central Europe, and on Physical Geography, on Mondays and Thursdays respectively. He is also giving an extension course in the town on the Great Explorers, which is largely attended.

Sir Ernest Clarke, Gilbey Lecturer, gives his second series of lectures on Agricultural History and Economics on Thursdays during February, at noon, in St. John's College.

Mr. Osbert Salvin, F.R.S., and Mr. Ainger, Master of the Temple, have been elected to Honorary Fellowships at Trinity Hall.

MR. JOHN D. ROCKEFELLER has just given the Chicago University 200,000 dols., this being in addition to many previous gifts.

THE following are among recent appointments:—Dr. Julius Istvánffy to be professor of botany at Klausenburg; Dr. Alexander Mágócsy-Dietz to be assistant professor of botany at Budapest; and Prof. Dr. Zacharias to be director of the Botanic Garden at Hamburg.

THE Finance Committee of the Corporation have recently reported on the application of the Council of the City and Guilds of London Institute for a renewal of the grant from the Corporation to the funds of the institute. They state from inquiry that the work of the institute has been successfully and economically managed, and the results achieved are fully commensurate with the expenditure involved. The Corporation have, in consequence of this report, voted 400*l.* in respect of last year towards the funds of the institute, to be devoted to the Finsbury Technical College.

A COPY of the Calendar of the University College of Sheffield has been received. It will be remembered that the present College was constituted by Royal Charter last May, and was formed by the amalgamation of three pre-existing institutions—the Firth College, the Sheffield Technical School, and the Sheffield School of Medicine. These institutions had previously worked hand in hand, although under independent governing bodies. By the charter they were merged into one corporation with a single Court of Governors. The new Calendar shows that the College is doing valuable work by providing the people of Sheffield and the district with the means of higher scientific and literary education by University methods of teaching.

AT a meeting of Convocation of the University of London on Monday, the report of the special committee appointed to consider the Commission Bill was adopted. After a discussion the following resolution, recommended by the special committee and moved by Dr. J. B. Benson, was carried, an amendment to it being rejected by seventy-six votes to forty-two: "That this House accepts the scheme embodied in the London University Commission Bill, 1897." The special feature of the resolution adopted rests upon the fact that it was supported by one of the sections that had always hitherto opposed the Cowper scheme. The opponents belong to two classes: the no change—that is, the two Universities section, who are still irreconcileable, and the section which favoured procedure by charter, and not by statutory commission. It was this section that was mainly responsible for the compromise embodied in the Bill of last year—a compromise which has been accepted by all the bodies concerned, and which Convocation has now approved.

THE annual general meeting of the Incorporated Association of Head Masters was held on Thursday last. Resolutions were passed referring to the new regulations of the matriculation examination of the University of London, the dates of scholarship examinations at Oxford and Cambridge, and the training of teachers. At the second day's meeting of the Association, this year's president, the Rev. A. R. Vardy, Head Master of King Edward's School, Birmingham, delivered an address in which he referred to some of the more important educational work accomplished by the Association during the past year. The Rev. R. D. Swallow, in moving "That this Association approves the steps taken by its representatives at the Delimitation Conference held at the Education Department, and hereby adopts the joint memorandum as agreed to at the conference," remarked that the conference, though under the chairmanship of Sir G. Kekewich, was unofficial. It was understood by all that State aid would be needed by secondary schools if they were to take their proper place. The great aim recognised in the memorandum was that the object of secondary schools was to form character in its fullest sense. As to application of principles, the masters of higher grade schools had acknowledged that there must be differentiation. The higher grade schools accepted a place as definitely higher primary schools. These schools had also accepted the assignment of scholarships to primary and secondary schools, and claimed no exclusive use of public funds. The Association also accepted the position that, being primary, these higher grade schools should also be free. There was also a common agreement as to a central authority. After some discussion, the resolution was adopted. A resolution was also carried to the effect that Parliamentary assistance was needed both for the cost of annual maintenance and the provision and equipment of adequate buildings for secondary education.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 16, 1897.—"On the Thermal Conductivities of Single and Mixed Solids and Liquids, and their Variation with Temperature." By Dr. Charles H. Lees, Assistant Lecturer in Physics in the Owens College.

These experiments were undertaken with a view to determining the effect of temperature on thermal conductivities, and the relation between the conductivity of a mixture and the conductivities of its constituents. About thirty solids, liquids, substances near their melting points, and mixtures of liquids, were tested between temperatures of 15° and 50° C., and the following statements embody the results:—

(1) Solids not very good conductors of heat in general decrease in conductivity with increase of temperature in the neighbourhood of 40° C. Glass is an exception to this rule.

(2) Liquids follow the same law in the neighbourhood of 30° C.

(3) The conductivity of a substance does not invariably change abruptly at the melting point.

(4) The thermal conductivity of a mixture lies between the conductivities of its constituents, but is not a linear function of its composition.

(5) Mixtures of liquids decrease in conductivity with increase of temperature in the neighbourhood of 30° C., at about the same rate as their constituents.

"On the Biology of *Stereum hirsutum*, Fr." By H. Marshall Ward, Sc.D., F.R.S., Professor of Botany in the University of Cambridge.

The author has cultivated the mycelium of this fungus obtained from spores, on sterilised wood, and after several months the cultures developed yellow bosses which proved to be the hymenophores bearing the basidia. This fungus has not hitherto been made to produce spores in cultures, and Basidiomycetes generally have rarely been made to do so. The actions of the mycelium on the wood of *Æsculus*, *Pinus*, *Quercus*, and *Salix* are also examined, and this is, so far as known, the first time this has been done with pure cultures.

Mathematical Society, January 13.—Prof. Elliott, F.R.S., President, in the chair.—The President informed the Members of the recent decease of Signor Brioschi, a Foreign Member of the Society, gave a slight sketch of some of his work, and dwelt upon the loss occasioned by his death to the mathematical world. He then read a letter drawing attention to what was proposed to be done in founding a "Sylvester-Memorial" medal, to be awarded triennially by the Royal Society.—Mr. Love, F.R.S., communicated a paper, by Mr. B. Hopkinson, on discontinuous fluid motion; and Mr. S. H. Burbury, F.R.S., gave a sketch of his paper on the general theory of stationary motion in a system of molecules.—The following papers were briefly communicated from the chair:—Note on a property of Pfaffians, Mr. H. F. Baker; on the intersections of two conics of a given type, and on the intersections of two cubics, Mr. H. M. Taylor; on the continuous group defined by any given group of finite order, Prof. W. Burnside, F.R.S.; on those transformations of coordinates which lead to new solutions of Laplace's equation, Prof. Forsyth, F.R.S.—Mr. G. B. Mathews, F.R.S., exhibited copies of a figure connected with Prof. F. Morley's paper (on the Poncelet polygons of a Limaçon, November 11, 1897).

EDINBURGH.

Royal Society, December 20, 1897.—The Hon. Lord McLaren in the chair.—Dr. C. G. Knott read an obituary notice of the Rev. John Wilson.—Dr. Noël Paton communicated the result of a series of investigations on the life-history of salmon in fresh water. The work was carried on in the Research Laboratory of the Royal College of Surgeons, Edinburgh, for the Scottish Fishery Board, and the results will be embodied in a report to that Society. The following are the names of those responsible for the different parts of the investigation: Drs. F. D. Boyd, J. C. Dunlop, A. L. Gillespie, E. D. W. Greig, G. L. Gulland, Mr. S. C. Mahalanobis, Miss M. J. Newbigin, and Dr. Noël Paton. The objects of inquiry were: To determine whether salmon feed in fresh water; to investigate the factors causing the migrations of the salmon from sea to river, and river to sea; to study the cause of the migrations, and to investigate the chemical changes of the salmon in fresh water. With regard to the first question—Do salmon feed in fresh water?—it is shown that, in fish which have been in fresh water, changes occur in the mucous membrane of the alimentary canal, the cells undergoing degeneration, and desquamation. The digestive activity is feeble; there is a greater number of micro-organisms found in the stomach and intestines, and the proportion of putrefactive organisms is greater. This last may be accounted for by the absence of acid connected with the low digestive power. As to the second and third points of inquiry—the cause and course of migration—the changes in the weight and condition of salmon, from the estuaries and upper reaches, have been studied during the season. There is evidence that migration is not caused by the *nisus* generations but by the state of nutrition. The chemical changes which take place in salmon are interesting. There is a disappearance of solids from the muscles, which is far more than sufficient to yield the solids required by the growing ovaries and testes, and the disappearance of fat from the muscles is more than sufficient to yield the fat of the ovaries. The muscles do not undergo fatty degeneration, but fat is stored between the fibres and in the fibres, and afterwards discharged or used up. The fats are the most important source of the energy of muscular work. The "curd" is due to an excess of soluble proteids, which diminish in the muscles as the season advances. The proteid lost from the muscle is far more than sufficient to yield the proteid of the ovary and testis. The phosphorus stored in the muscles is just sufficient to yield the phosphorus of the growing ovary, but the iron stored in the muscle is not sufficient to yield the iron of the ovaries. Changes in the food value of the fish, and the nature of the pigments in the flesh and ovary are also subjects of investigation.—A note on the passage of water and other substances through india-rubber films, by Dr. R. A. Lundie, was communicated by Prof. Tait.

PARIS.

Academy of Sciences, January 10.—M. A. Chatin delivered the presidential address, in which, after some remarks on botanical classification, he gave brief accounts of the work of members and associates lost by death during the past year, MM. D'Abbadie, Des Cloizeaux, and Schützenberger. The prizes for the year 1897 were awarded as follows:—Francœur Prize, for Geometry, to M. G. Robin; the Poncelet Prize, to M. R. Liouville, for his work on mathematics and mechanics. In Mechanics, the Extraordinary Prize of six thousand francs, between MM. Gossot, Liouville, Decante, and Chéron; the Montyon Prize between MM. Bourguin, Pavie, and Pigache; and an encouragement from the funds of the Plumey Prize to MM. Brillé and Girard. The Fourneyron Prize, on the theory of the motion of bicycles, was not awarded. In Astronomy, the Lalande Prize to M. Perrine for his discoveries of comets; the Damoiseau Prize to M. Hermann Struve; and the Valz Prize to M. Louis Fabry. In Physics, the La Caze Prize to M. Ph. Lénard for his researches on the kathode ray. In Statistics, a Montyon Prize is divided between M. Gustave Bienaymé and MM. Vincent and Burot; a very honourable mention being accorded to M. Lepage and an honourable mention to M. Baudran. In Chemistry, the La Caze Prize to M. Sabatier for his researches on the sulphides of the alkalis and alkaline earths, of boron and of silicon, on the thermochemistry of the hydrated metallic chlorides, on metaphosphoric and nitrosodisulphonic acids, and on the action of the oxides of nitrogen upon metals; the Jecker Prize to M. Haller for his researches in organic chemistry, especially on the derivatives of camphor. In Mineralogy and Geology, the Grand Prize for the Physical Sciences to M. Joseph Vallot for his researches on the meteorology and geology of the High Alps and Pyrenees; the Bordin Prize to M. G. Pruvot for his works on the depth and fauna of the Gulf of Lyons, and the Delesse Prize to M. Œhlert for his paleontological work. In Botany, the Desmazières Prize to M. Jacob Eriksson for his researches on the mode of life and propagation of the numerous forms of blight which attack cultivated graminaceous plants; the Montagne Prize to M. Bourquelot for his work on the physiology of fungi, and the Thore Prize between M. Louis Bordas and M. Sappin-Trouffy. In Anatomy and Zoology, the Savigny and the Da Gama Machado Prizes are not awarded, but honourable mention is accorded to the work of Mdme. la Comtesse de Linden. In Medicine and Surgery, Montyon Prizes are awarded to M. Gaucher for his memoirs on the pathogeny of nephritis and on the diseases of the skin; to M. Zambaco for his work on leprosy in Constantinople; to MM. Rémy and Contremoulins for their Atlas of Radiophotography; and to MM. Marie and Ribout for their radiographic work. Mentions are accorded to M. Fabre-Domergue, MM. Bosc and Vedel, and a third mention to M. Lapique; the Barbier Prize is given to M. de Rochebrune for his treatise on African toxicology, and a mention to M. Lucet for his memoire on *Aspergillus fumigatus* in domestic animals and in incubating eggs; the Bréant Prize to MM. Burot and Legrand for their works on marine epidemics and on mortality in the Colonial army; the Godard Prize to MM. Beauregard and Boulart for their researches on the genito-urinary organs of the Cetacea; the Parkin Prize to Dr. Augustus Waller for his studies relating to the action of carbonic acid and other gases upon the negative variation of excited nerves; the Bellion Prize between M. Auguste Pettit for his researches on the suprarenal capsules, and M. Peron for his anatomical and experimental researches on the tuberculosis of the pleura; the Mège Prize to M. Ph. Tissié; the Lallemand Prize between M. Henri Meunier for his study of the part played by the nervous system in infection of the pulmonary apparatus and M. Gustave Durante for his work on secondary degenerations of the nervous system. Honourable mentions are accorded to M. Voisin, MM. Onuf and Collins, and to M. A. Mercier. The Baron Larrey Prize is awarded to M. Auffret for his monographs on the help to be given to the wounded and shipwrecked in maritime war. In Physiology, the Montyon Prize for experimental physiology is given to M. Delzenne for his works on the coagulation of the blood, the La Caze Prize to M. Röntgen for the discovery of a new and powerful instrument of physiological and therapeutical research; the Pourat Prize to M. Kaufmann; the Martin Damourette Prize to M. L. Guinard for his memoirs on the physiological effects of some of the opium alkaloids, and on the causes of certain accidents in anæsthesia; and the Philipeaux Prize to MM. Courtade and Guyon. In Physical Geography, the Gay Prize is accorded to M. Charles Flahault for his memoir on the study of the French Mediterranean region from the point of view of the geographical distribution of plants. Of the General Prizes, the Montyon Prize (unhealthy trades) is not awarded this year, but mentions are accorded to MM. Masure, Arnaud, and Magitot. The Cuvier Prize is given to Prof. Marsh for his geological work in the United States; the Trémont Prize to M. Frémont; the Gegner Prize to M. Paul Serret; the Petit D'Ormoy Prizes to the late M. Tisserand (Mathematical Sciences); and M. Gosselot (Natural Sciences); the Tchiatcheff Prize to M. Obrutschew; the Gaston Planté Prize to M. André Blondel; the Cahours

Prize between MM. Lebeau, Hébert, Tassilly, and Thomas; the Saintour Prize to M. G. André; the Prize founded by Mdme. La Marquise De Laplace to M. Crussard, and the Prize founded by M. Félix Rivot to MM. Crussard, Gourguechon, Bertrand, and Bruneau.

NEW SOUTH WALES.

Royal Society, November 3, 1897.—The President, Henry Deane, in the chair.—The effect of temperature on the tensile and compressive properties of copper, by Prof. Warren and Mr. S. H. Barraclough. This investigation was carried out on some fifty copper test pieces. The temperature range attained was from 25° F. to 535° F., the temperatures being measured by certified mercurial thermometers. The chief conclusions arrived at were: (*a*) The relation between the ultimate tensile strength and the temperature may be very closely represented by the equation $f = 32{,}000 - 21\ t$, where f is the tensile strength expressed in pounds per square inch, and t is the temperature expressed in degrees F. (*b*) Temperature does not affect the elongation or contraction of area in any regular manner: and at any one temperature the variation in these two quantities is so variable for different specimens that no particular percentage could be included in a specification for the supply of copper. (*c*) The elastic limit in tension occurs at about 5400 lbs. per square inch: this limit probably decreases rapidly with increase of temperature, but the differences in the behaviour of individual specimens are so great as to prevent the determination of the relationship between the two quantities. (*d*) The elastic limit in compression occurs at about 3200 lbs. per square inch: it decreases with increase of temperature, the relationship between the two being more regular than in the tensile tests. (*e*) The rate of permanent extension and compression increases rapidly with increase of temperature.—Aurora Australis, by H. C. Russell, C.M.G., F.R.S. This paper contained a list of auroral displays in the southern hemisphere during 1897, also a detailed account of one which was observed by the captain and officers of the R.M.S. *Aorangi*, on April 20, 1897, when the ship was in long. 96° W. and lat. 47½° S.—The basalts of Bathurst and the neighbouring districts, by W. J. Clunies Ross. In this paper the character of the basalt occurring in the neighbourhood of Bathurst, on the Bald Hills, and other hills in the vicinity, was described. Specimens from various localities have been obtained, microscopic sections cut from them, and chemical analysis made. It has been found that there are some differences in the microscopic structure of the rocks from hills close together, but the chemical analysis shows them to be all closely related. The silica was found to be about 47 per cent., but reached 50 per cent. on Mount Pleasant. The alumina, oxide of iron, lime, and magnesia were also determined. For comparison with the Bathurst basalt, which no doubt originally flowed as a lava from some centre of volcanic activity, and in order to trace the source from which it came, specimens were examined from all the places within forty miles of Bathurst, where basalts are known to occur.

THE HOPE DEPARTMENT AT OXFORD.

The Hope Reports. Vol. i., 1893-97. Edited by Edward B. Poulton, M.A., F.R.S., Hope Professor of Zoology in the University of Oxford. (Printed for private circulation.)

SINCE the death of Prof. Westwood and the appointment of his successor, the editor of the volume of Reports under consideration, the Hope Museum has gradually been undergoing expansion and regeneration. The collections are being overhauled and reclassified; the types are being identified as far as possible and carefully labelled, and the special British collections are being rearranged, so as to preserve their historical interest. This development of the department under the care of Prof Poulton has been noted with satisfaction by those specialists who from time to time visit Oxford: and although the endowment, both for curatorship and equipment, is very limited, it must be conceded that the present Professor is doing his best to carry out the objects for which a museum of this kind exists, viz. to preserve specimens in such a way as to enable them to be available for use by students with the confidence which attaches to authentic records of date, locality and captor. This, at least, is the ideal which the Professor has set before himself, and it is only a matter of profound regret that the advanced years and declining health of the late distinguished occupant of the Rev. F W. Hope's foundation should have thrown upon his successor such an immense amount of purely mechanical labour. A good beginning has been made with the Lepidoptera with the co-operation of Colonel Swinhoe, Dr. F. A. Dixey, Prof. Sidgwick, and others; but many years must elapse before the other and less favoured groups are reduced to anything like the same degree of order.

The conditions attaching to such an endowment as that of Mr. and Mrs. Hope have with the advancement of science and the increase in the number of private collections undergone complete modification. Although as a collection of insects of all orders the museum as it exists is second only in rank to the National Collection, the means provided are barely sufficient for its maintenance and leave very little for its increase. With such competing forces as the British Museum, Mr. Walter Rothschild's museum at Tring, and the wealth of many other private collectors, it is hopeless to look for any substantial additions to the Oxford collections excepting through individual benefactors. It is very encouraging, therefore, to find in the two official reports of the Professor on the work of his department, that many valuable contributions have been made by entomologists since he came into office, and more particularly may be mentioned the magnificent addition to the butterflies presented by Messrs. Godman and Salvin, which is characterised as "the largest accession to the department during recent years," and which was formally accepted by a decree of Convocation on May 11, 1897, when a further decree conveying the thanks of the University to the donors was also passed unanimously.

The foregoing remarks relate to the work accomplished in the development of the museum as a museum; but there is another side to the work of the Hope Department which must not be lost sight of, and of this side we are reminded by the volume of Reports. This volume is most appropriately prefaced by the portraits of the makers of the department, Mr. and Mrs. Hope and the late Prof. Westwood. In his prefatory remarks the editor says:—

> "In the present state of zoological science, it is impossible to make use of existing knowledge in the careful study of a large amount of material without adding to that knowledge. Research after the various kinds of knowledge which have been prized by mankind during successive ages was of old the prominent function of the University; and although obscured during the recent generations by excessive devotion to the examination system, may still be claimed as an academic duty and high privilege second to no other in importance."

With this statement every science worker in this country will agree, and the signs of activity displayed in this new departure on the part of the Hope Professor will be cordially welcomed. The papers composing this volume are sixteen in number, and are reprints of papers which have already appeared in the publications of various societies. For the most part these papers embody "researches" as distinguished from purely descriptive systematic work, and that is why we consider the issue of the volume to mark a new departure. The contents of the various papers are already before the scientific public, and need only be mentioned here. Prof. Poulton's contributions consist of his address to the Zoological Section of the British Association at Liverpool on the age of the earth, his address on "Theories of Evolution" to the Boston Society of Natural History, his paper on Dr. Prichard's anticipation of modern views of evolution, from *Science Progress*, papers on the courtship of European Acridiidæ, and on the sexes of larvæ emerging from successively laid eggs of *Smerinthus populi* from the *Transactions* of the Entomological Society of London, and a paper on the colours of Lepidopterous larvæ derived from plant pigments, from the *Proceedings* of the Royal Society. Dr. F. A. Dixey also presents us with most encouraging signs of scientific activity from the department. Five papers relating respectively to mimicry, to the phylogeny of the Pierinæ, and to the interpretation of Mr. Merrifield's experiments on temperature variation in Lepidoptera are contributed by him. Another set of contributions are from the pen of Mr. Garstang, who writes on the habits and respiratory mechanism of *Corystes*, on the function of the antero-lateral denticulations of the carapace in sand-burrowing crabs, and on the morphology of the Mollusca. Mr. Garstang's papers on Crustacea should be read by all who are interested in the question of the utility of specific characters. The only paper approaching systematism is by Mr. Schaus, who gives a list of Mr. Walker's American types of Lepidoptera in the museum, and for this lepidopterists on both sides of the Atlantic will be grateful.

It will be gathered from this notice that the Hope Professor has rendered a good account of his office since his appointment. The plan of issuing such Reports, which has been adopted from the example set by the Linacre Professor, is an excellent one, and cannot but help to keep alive the public interest in the work of the department. With the lapse of time and the arrangement and coordination of the collections we may look for further contributions from Prof. Poulton himself in those branches of insect bionomics with which his name is so widely connected.

R. M.

WEAPONS OF EARLY MAN IN BRITAIN.

The Ancient Stone Implements, Weapons, and Ornaments of Great Britain. By Sir John Evans, K.C.B. Second edition. Pp. xviii + 747. (London: Longmans, Green, and Co., 1897.)

FOR some years past it has been felt by students of anthropology that the limits of their science were being pushed so far in every direction by various enthusiastic workers in almost every country of the inhabited world, that it was high time for some competent hand to gather together the facts which lay scattered broadcast in the publications of learned societies and private students, so that they might be available for general use in a collected form. It seems that this idea also filled the mind of one, at least, of our veteran teachers, and the result of its existence is the second edition of Sir John Evans' famous work on the "Ancient Stone Implements, Weapons, and Ornaments of Great Britain." It is now some twenty-five years since the first edition of this valuable book saw the light, and the accuracy and plain statement of facts, which were its chief characteristics, secured for it at once a place of high authority. In those early days of the history of British stone-lore scientific collectors of facts were few, and men like the late Sir Wollaston Franks, the Rev. William Greenwell, and Mr. J. Anderson of Edinburgh, who attempted to arrange their specimens with a proper regard to hard facts, were looked upon with suspicion by a large mass of collectors and "antiquaries" whose chief interest in antiquities lay not in the objects themselves, but in the wonderful stories which they could tell about them. A visit to certain local museums not many scores of miles from London will to this day show what measure of learning was possessed by those who labelled and arranged them about thirty years ago, and we make bold to say that general ignorance and specific blunders in such matters can only be cleared away by the publication of good works, such as that before us, written in plain language and published at a reasonable price.

Sir John Evans' book is so well known that it would be a waste of the reader's time to attempt to describe it here, but it will not be out of place to note wherein the second edition differs from the first. Many of the excellent illustrations by Mr. Swain have been retained, but a number of new ones have been added; the text, which filled six hundred and twenty-two pages in the first edition, now fills seven hundred and nine. The indexes, which formed such a useful part of the first edition, are more than double as large, and many a reader will thank Mrs. Hubbard, who is responsible for them, for lightening his labours. In general form, size of type, &c., both editions are alike.

But in the quarter of a century which has passed since Sir John Evans issued the first edition of his work, many striking discoveries of stone weapons and other objects have been made. Excavations which have resulted in "finds" of great value have been carried on in many parts of England, whilst diggings in Egypt and elsewhere in the East have brought to light facts which in some cases have upset our most cherished and most ancient convictions. With new facts coming to hand continually, Sir John Evans has found it possible to generalise and to make deductions such as would, a few years ago, have been impossible; and a perusal of some of the chapters of his book reveals the startling fact that the inhabitants of parts of Asia, Africa, and Europe, situated at very remote distances from each other, made their weapons of the same materials, in the same shape, and in the same way. Indeed, it is very hard not to assume that such peoples either came from the same stock, or had some means of communication which until now has remained unsuspected.

In addition to well-known collections such as those of the Rev. W. Greenwell, General Pitt-Rivers, and certain public museums, Sir John Evans has drawn his facts from the examination of other collections in this country and on the continent which, fortunately, he has had time and opportunity to visit; besides these, he has been in communication with scholars and students in many parts of the world who have forwarded him antiquities which they have found or come across, and he has thus been in an excellent position to read, mark, and note the results of his observations for the benefit of the readers of the second edition. For the collector pure and simple the section of the book which ends on p. 639 will be more important than the rest, but for the general student who interests himself in the questions of the antiquity of man and the date of his appearance upon earth, and in theories of river-drift and flood-deposit, the chapters which follow will prove the greatest attraction. In only a few small points, in obedience to the authority of new information, Sir John Evans has modified the views which he expressed in his first edition; this fact, taken together with the number of discoveries made in the realm of British stone-lore during recent years, shows how carefully his work was conceived and executed. Our thanks are due to him for making available to each and all the stores of his mature learning and wide experience, and we can only hope that at some future period he may see his way to put on record some of the deductions which he must have made on many points, and the theories on difficult problems which he must have formed. Coming from him they would have a special value.

CLIMATOLOGY OF THE GLOBE.

Handbuch der Klimatologie. Von Julius Hann. Second edition. 3 vols. Pp. 1360. (Stuttgart: Engelhorn, 1897.)

THIS work, which belongs to the series of "Geographischer Handbücher" issued by Dr. Ratzel, will be welcomed by all meteorologists. It is the second edition of the work under the same title which appeared in 1883. That it has been entirely rewritten and enlarged appears from the fact that while the original single volume contained 764 pages, the work has now grown to three volumes, numbering, in all, 1360 pp. On reading it one cannot but be astonished at the extent of erudition and research which is displayed on every page.

Naturally, in a work dealing with the climatology of the whole globe, we do not expect to find detailed tables of temperature or of rain for every country; what we do find are careful excerpts of data from typical stations, illustrated by frequent extracts from travels and other works describing personal experiences in distant regions. Thus, for Siberia we have copious citations from Middendorff and Adolph Erman, for Hindostan from Blanford, for Java from Junghuhn, and so on.

The first volume, 400 pp., deals with the main factors of climate, and then passes on to general climatology. It treats, firstly, of solar climate, or that which would result from the action of the sun alone; and, secondly, of physical climate under the two heads of (*a*) Land and Sea Climate and (*b*) Mountain Climate. On the latter subject Dr. Hann is, admittedly, the highest living authority, and his remarks on the effect of mountains, on such winds as the Scirocco, the Bora, and the Mistral, as well as on the various air movements, in different directions in different countries, which are all classed under the generic term of Föhn winds, are well deserving of careful study.

Dr. Hann points out that every spot along the northern Mediterranean shores, which is famed for the mildness of its winter climate, owes this entirely to the immunity from the access of cold winds afforded to it by a mountain range in close proximity.

Vol. i. closes with a brief notice of the various theories of climatic changes, cyclical and otherwise, which have of late been put forward by Croll, Brückner, and others.

Vol. ii., with 384 pp., is devoted to the climatology of the tropics. This is necessarily treated in a more or less incomplete manner, for while the data for the interior of tropical Africa are fragmentary, next to none are attainable for the entire tropical region of Brazil, and very little for the tropical Pacific Islands.

To show what knowledge we have already gained of the climates of the east and west coasts of Africa, respectively, in low latitudes, we may say that the east and west coasts each occupy some fifty pages, while the interior is but briefly discussed.

Vol. iii. is even fuller than its predecessors, mounting up to 572 pages. It deals with the meteorology of the temperate and frigid zones. For the former, at least, the literature is far more abundant than that for the tropical countries, and a careful selection has been made.

The sections on East Siberia and on the United States are especially interesting, as showing how the difference in the trend of the mountain chains affects the climate of each region. The chain in the west of the two Americas lies close to the coast, and sweeps westwards towards the Bering Straits, whereas in Europe the Norwegian mountain line turns to the eastward. Accordingly, in the New Continent the influence of the Pacific Ocean is reduced to a minimum, while in the Old that of the Atlantic extends far inland.

Comparing the United States with Eastern Asia, we find that the whole of the States are exposed to the visitation of icy northerly winds owing to the absence of cross-mountain ranges of any considerable altitude. In Asia high mountains and tablelands effectually check the outflow of chilled air from the Siberian centre of cold, about the valley of the Lena.

The notices of Chili, Argentina, and the whole southern part of South America are extremely interesting reading.

The account of Arctic and Antarctic meteorology is very full, and as the data from all the expeditions of the years 1882-83 have been utilised, the information afforded is much more complete than any before presented to the public. Dr. Hann expresses his regret that the only publication of the scientific results of the English expedition of 1875-76, under Sir G. Nares, has been in a Blue-book, and is therefore almost inaccessible to men of science.

The entire work is eminently what the Germans call "epoch-making," and it is only to be regretted that, as it is in German, readers in England will be but few.

OUR BOOK SHELF.

Natürliche Schöpfungs-geschichte; gemeinverständliche wissenschaftliche Vorträge über die Entwickelungslehre. Von Ernst Haeckel. Ninth edition. Pp. lxii + 831. Portrait and thirty plates. (Berlin: Georg Reimer, 1898.)

This well-known book has now reached its ninth edition. The original form is retained, but many corrections have been made, and the phylogenies have been brought up to date according to Prof. Haeckel's interpretation of newly-ascertained facts.

The author's aim is to simplify the enormous mass of observations, reasonings and theories which we call biology, and to show that it can all be explained by a relatively few general principles. The worker at any special group of plants or animals will often, perhaps usually, find it impossible to satisfy other specialists as to the systematic relations of all the forms on which he has been engaged, or to clear up those vestiges of remote history which some of them may present. Haeckel, however, does not hesitate to deal with the whole animal and vegetable kingdoms, placing and deriving all the chief groups. Most philosophical naturalists find it hard to explain any fact of nature adequately, and put forth their conclusions timidly, as those who look for a day of fuller knowledge. Haeckel offers us a theory of development, by which all the chief groups of biological phenomena can be "mechanically explained and understood" (p. 790). This cheerful conviction that we already hold the main clues to a philosophy of nature is very engaging to those who have no great sense of responsibility as teachers or writers; it rouses the most profound scepticism in those who have found by trial how little we can really explain. Haeckel's "Schöpfungs-geschichte" is based upon wide knowledge; it has been corrected many times; it is clear and persuasive. Nevertheless, there is no book of our own day of which we should more confidently predict that a future and not distant generation will find it grotesquely inconsistent with natural fact. There are books which after many generations still seem modern; Malpighi and Swammerdam have written such. There are also books which become antiquated in the life-time of the author, and to our mind the book before us is one. It wants altogether the reserve, scepticism and modesty which were the safeguards of Lyell and Darwin when treating subjects of such unfathomable complexity.

A special student, critically examining that one of Haeckel's phylogenies with which he is chiefly concerned, would, we believe, find that it rests upon daring and gratuitous assumptions. The present writer distinctly affirms that this is true of the table of articulates on p. 575, and of the table of insects on p. 595. Unfortunately, the criticism by which this opinion might be justified would be too technical, and especially too lengthy, for the columns of NATURE. L. C. M.

Analytic Geometry for Technical Schools and Colleges. By P. A. Lambert, M.A. Crown 8vo. Pp. xii + 216. (New York: The Macmillan Company. London: Macmillan and Co., Ltd.).

THE great prominence given in the earlier chapters to curve-tracing, and the fact that the plotting of both algebraic and transcendental curves takes precedence of more purely mathematical treatments of the line, circle, and conic, renders this text-book peculiarly adapted in many respects to the requirements of engineering and other students whose main object is to obtain a thorough drilling in graphic methods. Such a student would do well to be guided by a teacher, as some early sections and examples are rather hard for first reading. In the later chapters the author has attempted to give an account of the properties usually treated in books on "Analytical Conics," together with the graphic representation of imaginaries, and an introduction to analytical geometry of three dimensions. With this portion, he can hardly be said to have been so successful. His treatment of such matters as tangents, diameters, asymptotes, and poles and polars, is very incomplete, and not calculated to bring into prominence those general properties which render such lines of importance in the geometry of conics; indeed, we might go further and say that even where no actual inaccuracies exist in the text, it would require a previous knowledge of the subject in order to enable a student to read between the lines sufficiently to avoid falling into error. Moreover, too little attempt is made at "graduating" the course, easy and difficult sections alternating with each other, and there being rather a lack of that sequence and arrangement which is so helpful to the beginner. Those who find life too short to learn conics up to examination standard will, however, be able, by the aid of the examples and a little outside help, to obtain a very fair superficial knowledge of the subject.

The Valley of Zermatt and the Matterhorn. A Guide. By Edward Whymper. With illustrations and maps. Pp. xvi + 212. (London: John Murray, 1897.)

THIS compact little volume in paper covers is designed on the same plan as the author's Guide to Chamonix, which was recently published. From so prominent a mountaineer much may legitimately be expected in a guide to one of the greatest climbing-centres in the Alps, but it is almost a surprise to find so very much which is available for the tourist whose bent does not incline towards feats of physical endurance. The first chapter is devoted to the early history and rise of Zermatt, then comes a history of the Matterhorn in four chapters, in which Mr. Whymper nerves himself to tell once more the terrible tragedy of his first ascent. The practical part of the Guide follows; hints as to the best way of reaching Zermatt, particulars regarding the valley and the village, and a carefully arranged series of excursions from that favourite centre. Excursions from the Riffelalp and other places are also described, and the opportunity is taken of sketching the mountaineering history of Monte Rosa. This blending of historical associations and anecdotes with practical hints and instructions is perhaps the most interesting feature of the Guide.

With the exception of some lists of altitudes of peaks and passes, and a geological section of the Matterhorn with an explanatory note in French by Signor F. Giordano, there is no special attention bestowed on the scientific aspects of nature-study.

The illustrations are examples of Mr. Whymper's own art, and no more requires to be said concerning them.

Practical Forestry. By C. E. Curtis. Second edition revised. Pp. viii + 124. (London: Crosby Lockwood and Son, 1898.)

NO doubt a forester might gain some advantage from a perusal of this book, provided he read it with caution. But he would encounter several statements with which he would have a difficulty in agreeing. For instance, the author deliberately says, "To purchase trees, or to plant by contract, are also means to ensure failure." If that were true, it would be small wonder that the results of forestry are not in all cases satisfactory in England, where quite 90 per cent. of the plantations have been formed in the ways that the book condemns. A most serious slip occurs in the statement of the rule for ascertaining the cubical contents of a tree, where "square of the girth" appears instead of "square of the *quarter* girth." This would not mislead a practical man, but it might lead to most unpleasant consequences in the case of a student who made use of the book in preparing for an examination.

Agriculture in some of its Relations with Chemistry. By F. H. Storer, Professor of Agricultural Chemistry in Harvard University. 3 vols. Pp. iv + 620, iv + 602, and vi + 679. (London: Sampson Low and Co., Ltd., 1897.)

WHEN a book has passed through seven editions in ten years, and has grown from two to three volumes, there can be no doubt that it has been appreciated. This bulky work deals in a discursive way with the subjects of soil, manures, and crops, and with many things connected with the management of land; the feeding of animals is not discussed. A great deal of information is brought together: one admires the extent of the author's reading; but after a lengthy perusal of his diffuse statements we rise with the feeling that we have not gained any really scientific grasp of the subject. The matter placed before the reader has, in fact, not been digested, or the experimental results correlated; the book is a miscellany by a very well-informed man. One good feature of the book is its practical character; the intelligent farmer will probably enjoy it better than the man of science. R. W.

Glimpses into Plant-Life. An Easy Guide to the Study of Botany. By Mrs. Brightwen, F.E.S. Pp. 351. (London: T. Fisher Unwin, 1897.)

THIS is a pleasant little book, and will be read with interest by many who enjoy a country ramble or rural life from the naturalist's point of view. The authoress displays a first-hand acquaintance with the plants concerning which she discourses; and if there are occasional slips when she deals with matters physiological, they will be readily pardoned for the sake of the generally excellent character of the book. There are some errors, however, which might easily have been avoided, *e.g.* *aëroid* for *aroid*, on p. 62. Some of the photographs of trees and bark are decidedly good.

Premature Burial: Fact or Fiction? By Dr. David Walsh. Pp. 49. (London: Baillière, Tindall, and Cox, 1897.)

SO much news is published with the idea of creating a sensation, that Dr. Walsh's critical examination of some of the stories of premature burials is very welcome. The general conclusion arrived at is that "the theory of frequent premature burial is unsupported by exact evidence; in other words, it occupies the position of a mere popular belief or fable."

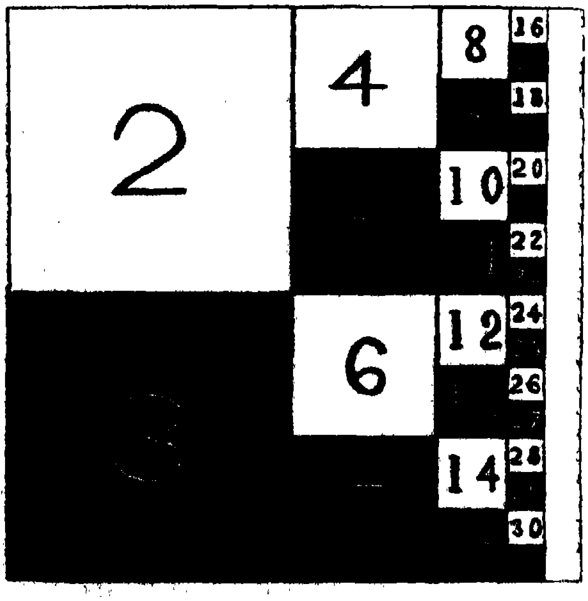
LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Diagram of Heredity.

THE law of heredity which was formulated by myself in a memoir entitled "The average Contribution of each several Ancestor to the total Heritage of the Offspring" (*Roy. Soc.*, June 3, 1897, and NATURE, July 8, 1897), and which, as I am exceedingly gratified to learn, is now strongly corroborated by an independent investigation, has recently been illustrated by a useful diagram. This was devised by Mr. A. J. Meston, of Allen Farm, Pittsburg, Mass., U.S.A., and communicated by him to the *Horseman* (Chicago, December 28), the leading American newspaper on horsebreeding, together with a popular explanation of the law in question. Believing, as I do, and I am not now alone in the opinion, that the law is a real advance in hereditary science, I think that Mr. Meston's diagram deserves a place in your columns, as conveying in a very intelligible form the chief features of the law.

These are that the total *heritage* of the offspring is derived as follows. The two parents between them contribute *on the average* one half of each inherited faculty, each of them contributing one quarter of it. The four grandparents contribute between them one quarter, or each of them one sixteenth; and so on, the sum of the series ½ + ¼ + 1/8 + 1/16 + &c. being equal to 1, as it should be. It is a property of this infinite series that each term is equal to the sum of all those that follow: thus ½ = ¼ + 1/8 + 1/16 + &c.; ¼ = 1/8 + 1/16 + &c., and so on. The prepotencies or subpotencies of particular ancestors, in any given pedigree, are eliminated by a law that deals only with *average* contributions, and the varying prepotencies of sex in respect to different qualities, are also presumably eliminated. Corrections for these can of course be made in any particular pedigree, taking care that the corrected series still amounts to 1 exactly.



It should be borne in mind that the word "Heritage" has a more limited meaning than "Nature," or the sum of the inborn qualities. Heritage is confined to that which is inherited, while Nature also includes those individual variations that are due to other causes than heredity, and which act before birth. Now individual variation in a race that is stable, must have a destructive as often as a constructive effect. Consequently its effects balance one another in *average* results, and disappear from a law which deals only with these.

The area of the square diagram represents the total heritage of any particular form or faculty that is bequeathed to any particular individual. It is divided into subsidiary squares, each bearing distinctive numbers, which severally refer to different ancestors. The size of these subsidiary squares shows the average proportion of the total heritage derived from the corresponding ancestors. The distinctive numbers are the same as those which I employed many years ago in connection with the "Family Records" with which I was at that time engaged: they were found both then and subsequently to be very convenient. The Subject of the pedigree is numbered 1. Thenceforward whatever be the distinctive number of an ancestor, which we will call n, the number of its sire is $2n$, and that of its dam is $2n + 1$. All male numbers in the pedigree are therefore even, and all female numbers are odd. To take an example—2 is the sire of 1, and 3 is the dam of 1; 6 is the sire of 3, and 7 is the dam of 3. Or, working backwards, 14 is a male who is mated to 15; their offspring is 7, a female, who is mated to 6; their offspring is 3, a female, who is mated to 2, and their offspring is 1, the Subject. The connection of all this with the binary system of notation is obvious, and need not be further alluded to. [In Mr. Meston's own diagram, the number 1 is assigned to the sire, and 2 to the dam, and so on. This detracts from the simplicity of the nomenclature, and therefore I do not adopt that part of his diagram.] The distinction between the male and the female squares is made still more conspicuous by colouring the latter; but, yielding to the exigencies of printing, I have replaced colour by printers' ink. So all male squares in my version of Mr. Meston's diagram have white grounds and black numerals, and all female squares have black grounds and white numerals.

The numbered squares could be continued indefinitely: in this small diagram they cease with the fourth generation, which contributes a 16th part of the total heritage, therefore the whole of the more distant ancestry, comprised in the blank column, contribute 1/16th also.

FRANCIS GALTON.

"Some Unrecognised Laws of Nature."

PRESSURE of important business has prevented me from writing ere this to claim space in your columns to enter a protest against the misrepresentations, as well as the whole tone, of the review—which appeared in your columns of the 9th ult.—of the above work, in which I have had the privilege of assisting during the past six years. Heretics have long learned not to expect mercy, or even to look for justice, at the hands of the orthodox. But from a reviewer who, oblivious of the proverb *Qui s'excuse s'accuse*, warned his readers that he at least was "not one to regard lightly the danger of summarily rejecting a germ of new discovery because it happens to conflict with orthodox opinions," we have a right to expect something very different from the venomous outpourings and direful warnings and threats that might flow quite naturally from an irate theologian when reviewing a work which strikes a blow at the very foundations of his dogmas and doxies. And this is the very head and front of our offending, that, heedless of authority, we regard "the whole doctrine of 'energy,' with all its astounding and contradictory corollaries," as absurd; as the product of the infantile, and necessarily anthropomorphic, imagination of primitive man; and that we have attempted to show how phenomena may be accounted for without having recourse to such figments of the imagination. In this we may have succeeded or not; the immediate verdict will largely, if not entirely, depend on the mental attitude of the judge, and for the ultimate verdict we must be content to wait. But your reviewer may find some comfort in the assurance that the *facts* of science, slowly accumulated through long ages, would not be affected, nor need the human race necessarily be plunged "once more into pre-Galilean ignorance," even if all the assumptions, the metaphysical conceptions—of ethers, "dead" matter, "animating" energy, &c.—on which current explanations of these same facts are based, were summarily consigned to the limbo of similar long-forgotten "working hypotheses." And it is these hypotheses we assail, not the facts.

Of his criticisms of the fundamental principles, or rather principle, on which all our explanations are based, I need say nothing, for I can safely leave them to the judgment of all who take the trouble to read our work. I may mention, however, that his review is itself a strong *a posteriori* verification of the law of persistence in its application to psychological phenomena. But I must protest against the, conscious or unconscious, misrepresentation involved in taking certain speculative conclusions—which in the light of current conceptions we know and point out must *appear* absurd—away from their context, and holding them up to ridicule as if they had been advanced as well-ascertained facts; and all these from a chapter the first words of which read—"This chapter will be mainly speculative."

In conclusion I would thank your reviewer for one useful piece of criticism in his eight-column notice—a notice, by the way, to say that the book is not worth noticing—in which he points out a loosely and badly worded paragraph on page 77, the real purport of which, however, is quite clear from what immediately precedes it. LEWIS H. BERENS.

Ilkley, January 15.

YOUR reviewer regrets an appearance of antagonism between himself and any one who has been genuinely endeavouring to improve natural knowledge, but he must point out that a great deal more study is necessary before a busy man like Mr. Berens can adequately inform himself what the present condition of scientific knowledge really is. O. J. L.

THE TOTAL ECLIPSE OF THE SUN.

IT will be some time before the complete results of the observations of last Saturday's eclipse can be made known, but it is extremely satisfactory that all the expeditions to India from this and other countries were favoured with perfect weather for the work. In places where the eclipse could only be partial the weather was not so favourable, for a telegram from Odessa (to the *Standard*) states that the observations of the solar eclipse in Southern Russia were not very successful owing to unfavourable weather. Only a few good photographs were obtained.

From a telegram received at Greenwich from Sohagpoor we learn that one of the official parties sent out by a joint Committee of the Royal Society and Royal Astronomical Society, consisting of the Astronomer Royal, Mr. W. H. M. Christie, and Prof. Turner, of Oxford, who were stationed at that place, were favoured with a perfectly clear sky, and were thus able to carry out completely the programme they had arranged; the same may be said of another official party, under the charge of Mr. Newall, of Cambridge, and Captain Hills, R.E., who were at Palgaon, near Wardha. The plates had not been developed, so it is impossible to say as yet how good the results are. Of Dr. Copeland, of Edinburgh, there is at present no news. As his station lay between those of the observers previously mentioned, it may be presumed that he also experienced a clear sky, and was, doubtless, equally successful.

A later telegram from Sir Norman Lockyer, who was at Viziadurg, on the West Coast, gives the results after developing the plates. It states: "Weather excellent, and all instruments satisfactorily employed with very good results except the integrating spectroscope. The temperature fell about 3° C. during the eclipse. It was not a dark eclipse, and very few stars were seen."

This news is expressed in fuller detail in the subjoined cablegram from Sir Norman Lockyer to the *Morning Post*:—

"The total eclipse of the sun was successfully observed at our Viziadurg station in the most perfect weather yesterday.

"At our station we had the invaluable assistance of one hundred and twenty-five officers, petty officers, and men from her Majesty's ship *Melpomene*, the observers being divided into twenty-one parties.

"As many as sixty photographs of the spectrum were taken, including four sets of ten instantaneous exposures at the beginning and at the end of the total phase.

"Some of these have been already developed, and are found to exhibit changes in the aspect of the chromosphere second by second at each of the four contacts.

"The corona was a very majestic spectacle, and it resembled that of 1896.

"As had been expected with so many sun-spots, there was no equatorial extension of the luminosity.

"A few stars were seen, but the darkness was not of sufficient intensity to necessitate the use of lamps.

"The longest streamer was a polar one, and had a length equal to four apparent diameters of the moon.

"This streamer was altogether a most exquisite structure.

"Mr. Eliot, the Meteorological Reporter to the Indian Government, and Mr. Pedler, of the Calcutta University, were members of our party.

"Mr. Pedler observed arc lines of iron in the lower corona.

"Lord Graham's cinematograph work has proved quite successful.

"The shadow of the moon on the earth was hardly seen in consequence of our atmosphere being too pure.

"The Collector at Ratnagiri and the officials of the Public Works Department attended, and rendered us every possible assistance."

The observations made at Talni by Mr. E. W. Maunder and Mr. C. Thwaites appear to have been very successful. The sky was beautifully clear. The light during the middle of totality was equal to full moon. The following is a statement of the results reported to have been obtained by the observers. The general shape of the sun's corona was like that seen in the eclipses of 1886 and 1896. The corona extended over two diameters from the sun, and its greatest extent was along the sun's equator. Photographs of the corona were obtained by Mrs. Maunder on a scale of four-fifths of an inch to the sun's diameter, and also on a scale of one-tenth of an inch, to get coronal extensions. The spectrum of the corona, chromosphere and prominences was successfully observed with an opera-glass fitted with a direct-vision prism in one of the eye-pieces. The chief coronal line was not seen on one limb of the sun, but extended to a considerable height at the other. The "flash" spectrum was seen both at the beginning and end of totality. Three photographs of the corona were obtained by Mr. Thwaites on a scale of seven-tenths of an inch to the sun's diameter. Mr. Thwaites also secured photographs of the corona on a scale of one-tenth of an inch to the sun's diameter. Good spectrum photographs were obtained by Mr. Evershed, who is also reported to have photographed the spectrum of the "flash" with a prismatic camera.

Observations of the eclipse were also made by a party from the College of Science, Poona, under the direction of Prof. K. D. Naegamvala, and by a party at Jeur, from the Lick Observatory, Mount Hamilton, U.S.A., under the direction of Prof. W. D. Campbell. It is reported that the sky was extremely clear, and that the observations were very successful. The light during the middle of totality is said to have been greater than that of full moon. The general shape of the corona was similar to that observed in 1886 and 1896. The corona extended to a distance of nearly two diameters from the sun, and its greatest extension was observed along the sun's equator.

A telegram from Dumroon states that the photographic observations made by the survey party there were entirely successful.

Seven good pictures of the corona were obtained during totality.

The following telegram was received from the Rev. J. M. Bacon, who was in charge of the British Astronomical Association party at Buxar:—

"On the Ganges weather perfect; observations satisfactory all round." Mr. Bacon appears to have taken a successful series of photographs with the cinematograph.

Other information received *viâ* New York indicates that the spectroscopic work of Prof. Campbell was also successful.

With such perfect weather, and the numerous powerful instruments utilised, the results of this eclipse expedition will form a unique record. A short account of some of the larger instruments should, therefore, be of interest.

For photographing the corona the Astronomer Royal was provided with a telescope having an object-glass of eight inches diameter, presented to the Royal Observatory some years ago by Sir Henry Thompson. This instrument gave an image of the sun's disc three inches in diameter on a large-sized photographic plate; the plates employed were such as would be most likely to show the delicate detail of the cloud-like structure close to the sun's limb.

Besides the photographs of the corona, Mr. Christie's photographs of the sun and moon, before and after totality, will, no doubt, be of much value to the theory of the lunar motion.

Another large telescope for photographing the corona was Dr. Copeland's 40-foot coronagraph, fixed up on trestles and directed to the sun, the required movement during totality being secured by a correct motion of the plate. The diameter of the sun's image given by this telescope is 4 inches.

For spectroscopic observations, the prismatic cameras with Sir Norman Lockyer's party were the most powerful. Never before during an eclipse have spectroscopes with so large dispersion and aperture been used. The 6-inch prismatic camera used by Mr. Fowler had two large prisms of 45°, instead of the one prism with which the results of 1893 were obtained, the dispersion being thus nearly doubled (Fig. 1). This added power will tell in many ways. By drawing out the spectrum into a band of twice the length the accuracy of measurement will be greatly increased. Further, remembering that the sky was slightly hazy in 1893, when eight coronal rings were photographed, and that the use of a still greater dispersion, by spreading out the continuous spectrum of the corona, will increase the chances of registering the fainter coronal rings, it is not too much to hope that the photographs taken during the eclipse will add much to our knowledge of the chemical nature of the corona.

A 9-inch prismatic camera, in charge of Dr. W. J. S. Lockyer, although of larger aperture than the 6-inch prismatic camera, had only one prism of 45°, giving a slightly greater dispersion than the 6-inch with one prism.

Each of these prismatic cameras was used in conjunction with a siderostat, and pointed to the reflecting mirror in such a way that the arcs of the chromospheric spectrum at the beginning and end of totality were at right angles to the dispersion. The accompanying illustration (Fig. 2) shows the 9-inch prismatic camera in this position.

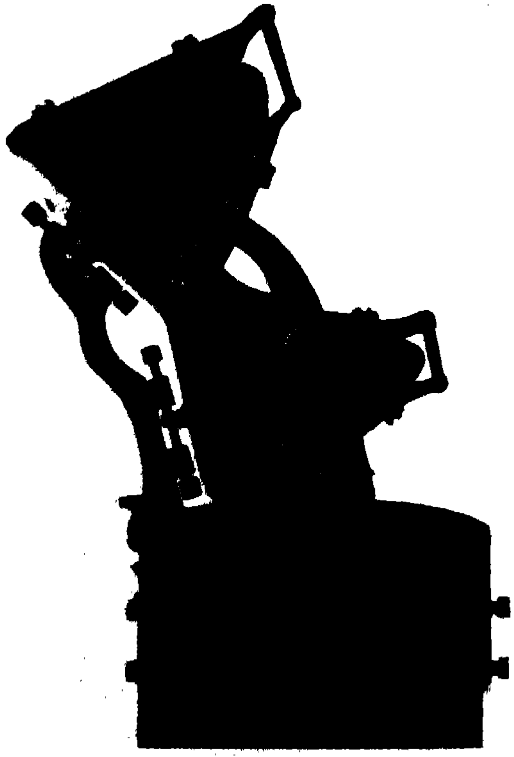


FIG 1.—Prisms of the 6-inch Prismatic Camera.

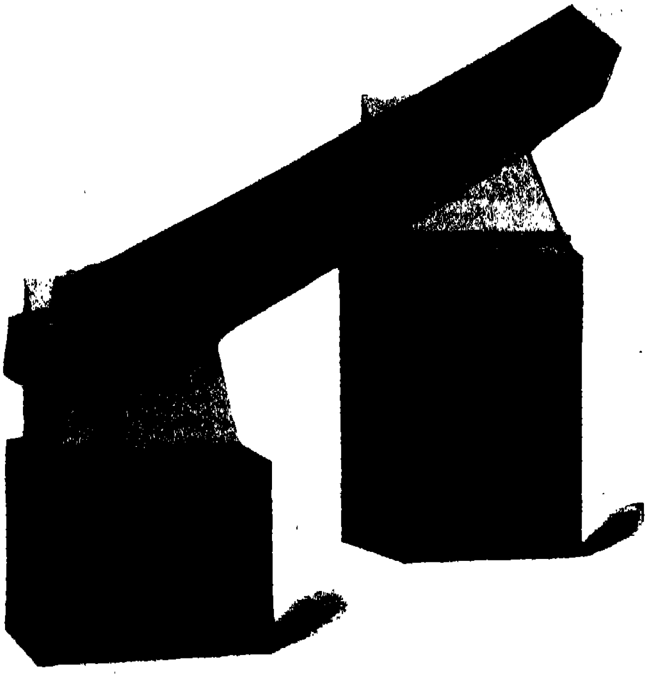

FIG. 2.—9-in. Prismatic Camera in position for the Eclipse.

Besides the prismatic cameras the eclipse camp at Viziadurg was equipped with other instruments for making a complete set of observations, and by the help of the officers, petty officers, and men from H.M.S. *Melpomene*, the whole of the instruments, including the coronagraph, with coelostat, integrating spectroscope, and other spectroscopes for visual work, have been used. Having previously been trained for all kinds of observations, these efficient volunteers have also made disc observations and drawings of the corona, and observed the effects of the eclipse on temperature, wind, landscape, and other natural phenomena.

The great interest taken in the eclipse in India paved the way for all parties to make their observations and erect their instruments with almost as much ease and facility as if they had been at home. The following letter from Sir Norman Lockyer to the *Morning Post*, on the "Preparations for the Expedition," shows that the Government of India rendered very valuable assistance to all the eclipse parties; and astronomers may well congratulate themselves upon the interest thus officially manifested in their work.

PREPARATIONS FOR THE EXPEDITION.

"On arriving at Port Said I received an important letter and enclosure from Mr. John Eliot, C.S.I., F.R.S., the Meteorological Reporter to the Government of India, who has been unceasing in his labours to further the coming observations. From these documents the final arrangements made by the Government of India may be gathered, and it must be acknowledged that they have been most admirably thought out, and are altogether such as should give the greatest amount of satisfaction to the world of science.

"The long thin line of totality, extending from Viziadurg to the Himalayas, will have, it appears, at least seven parties coming from England extended along it; three official parties and four parties consisting of members of the British Astronomical Association. The local assistance rendered by the Government of India will take the following shapes:

"(1) Accommodation for the observers and their assistants. If bungalows are not available, tents and huts will be erected, and will be available at once on arrival of the parties.

"(2) Messing arrangements, which will also be made before the arrival of the parties.

"(3) Ample supply of materials — bricks, Portland cement, planks, huts, &c.—for the erection of stands, platforms, &c., for the instruments, and of the sheds, which will probably be found necessary for the protection of the instruments. The materials will be arranged for beforehand, but the actual work will have to be done under the superintendence of the heads of the observing parties. Hence a Public Works Department subordinate, with a sufficient number of masons and carpenters, will be deputed for the purpose.

"(4) Portable dark rooms with supply of ordinary photographic materials for developing plates, &c.

"(5) Arrangements for protecting the instruments, &c., and also the observers from the intrusion of natives.

"(6) As many of the arrangements will have to be made beforehand, a European officer of sufficient standing will be appointed to carry out all that is required, and will be given full authority to make the necessary arrangements with the district officers, and be authorised to obtain the services (1) of a Public Works Department subordinate and workmen, (2) of a sufficient number of guards or policemen."

The latter clause of Mr. Eliot's letter appears to have been taken advantage of at most of the eclipse stations, so that in no instance have the observations suffered from the natives, either by the lighting of fires, thereby causing clouds of smoke, or any other interference.

With such a list of successes we may safely say that this eclipse, as befitting the last one of the century, has surpassed all previous records; but unlike many eclipses at the beginning of the century, it cannot be truly said that the event of Saturday was over at the end of the two minutes of totality. To many the eclipse has yet to begin, and will last for many months, during which time each line in the spectrum, each streamer of the corona, each prominence on the sun, will be analysed, little by little, to discover if we have similar streamers in other coronas, or identical lines in our laboratories. It may be confidently expected that the results obtained on Saturday will enable us to solve some of the enigmas of solar phenomena and constitution.

THE FORTHCOMING BRISTOL MEETING OF THE BRITISH ASSOCIATION.

A SUCCESSFUL conversazione was given on Thursday last, in the Victoria Rooms, Clifton, by the Mayor and Mayoress of Bristol (Sir Robert and Lady Symes) and the Local Executive Committee, with the object of stimulating interest in the approaching meeting of the British Association, on September 7, in Bristol. A programme of music by the Royal Artillery (Mounted) Band was arranged and admirably carried out. The Mayor, in a short and effective speech, bade a hearty welcome to his guests, among whom were the President-elect (Sir William Crookes, F.R.S.), the Mayors of Bath, Gloucester, Wells, and the Bishop of Bristol, together with many of the most influential Bristol citizens.

The local secretaries (Mr. Arthur Lee and Dr. Bertram Rogers), together with the local treasurer (Mr. J. W. Arrowsmith), aided by an influential and representative Executive Committee, have been for some time active in making preliminary arrangements for the meeting. The Victoria Rooms, Clifton, will be secured for the reception rooms and offices, the public lectures will be given in the large Colston Hall, and rooms for sectional meetings have been placed at the disposal of the Committee by the Museum Committee of the Corporation, the Council of University College, the Society of Merchant Venturers, the Charity Trustees, and the Bishop of Clifton. Other suitable rooms will be secured. It is proposed to arrange an exhibition of pictures in the Drill Hall, where a military band will play during the afternoons after the sectional meetings. Arrangements are also in progress for a biological exhibit at the Zoological Gardens in Clifton, in which Mr. E. J. Lowe, F.R.S., Dr. Harrison and Prof. Lloyd-Morgan are taking an active interest. It is hoped that the authorities of the Marine Biological Association will be able to show living marine organisms from their station at Plymouth. A fuller account of these arrangements will be communicated to NATURE when they are further advanced.

The excursions promise to be both varied and interesting. As at present projected, they include Bath, where the Mayor and citizens will entertain the visitors; Tortworth, where Lord Ducie will entertain a small party of geologists, and afford them special opportunities of examining the Silurian beds in that neighbourhood; Aust Cliff, with its fine exposure of Keuper, Rhætic, and the lowest beds of the Lias; Stanton Drew, with its megalithic remains, the Cheddar Cliffs and Caves, the sources of the Bristol water supply, the Severn Tunnel, Cadbury Camp, Swindon, Avonmouth, Wells and Glastonbury, where the Mayor of Wells, the Dean and Chapter, and residents will entertain the visitors to lunch, and the Mayor of Glastonbury will provide tea in the old Abbot's Kitchen. Other excursions to Salisbury and Stonehenge, Nailsworth and Stroud, Longleat, and Raglan Castle are under discussion.

The handbook is in active preparation, and its several sections have been placed in the hands of local authorities on the various subjects with which it deals.

It would seem, therefore, that the meeting at Bristol bids fair to be an interesting one, and that every effort will be made to render it also a successful one.

THE REORGANISATION OF THE UNIVERSITY OF LONDON.

THE influential deputation which was received by the Duke of Devonshire at the Privy Council Office on Monday will serve to remind the Government that the scheme for the reconstruction of the University of London as a teaching body has the support of the leaders in all branches of learning. The deputation was thoroughly representative, and its constitution shows the strength of the plea for a measure of educational reform of pressing importance.

The deputation was introduced by the Vice-Chancellor of the University of London (Sir H. E. Roscoe), and included Prof. Michael Foster (representing science), the President of the Royal College of Physicians (Sir Samuel Wilks), the President of the Royal College of Surgeons (Sir William MacCormac), Dr. Frederick Taylor (chairman of the delegates of medical schools), Lord Reay, Principal Rendall (of Liverpool University College), Dr. Crosby (City Corporation), Mr. Sidney Webb (chairman of the Technical Education Committee of the London County Council), Mr. Ralph Palmer (City Guilds), Mr. Warren (President of Magdalen), Sir Wolfe Barry (President of the Institute of Civil Engineers), Mr. Cozens-Hardy, M.P. (chairman of the General Council of the Bar), Sir A. Rollit, M.P., Sir Joshua Fitch, Mr. Anstey, Mr. Haldane, M.P., Mr. Frank Heath (Assistant Registrar of the University of London), and others.

The Duke of Devonshire's sympathy with the objects of the deputation is known to all who are interested in higher education in London; and though the reply he gave to the deputation was cautiously expressed, it is sufficient to justify us in believing that the Government will give prominence in the next Session to the scheme for the reorganisation of the University. The Duke of Devonshire pointed out that the Government did not need to be convinced as to the importance of the question, and that there are no political obstacles in the way; but the effect of the meeting on Monday will be to furnish the Ministry with additional force in urging upon Parliament the expediency of giving such moderate provision of time as may be necessary to overcome the small amount of opposition which still exists to the Bill for the reconstruction of the University.

With regard to the question whether the Senate of the University of London should ask for a new charter, which would carry out the objects required without the interposition of Parliament, or the appointment of a Royal Commission, the consensus of opinion is distinctly in favour of proceeding by statutory commission rather than by new charter. It was, perhaps, just as well that the question was raised, for it enabled the deputation to express the conviction of those who are directly interested in the development of the University, that the only practicable solution of the problem lies in procedure by a Statutory Commission Bill. For the sake of learning and the advancement of science, it is devoutly to be hoped that such a Bill will soon pass through both Houses of Parliament. That there are grounds for entertaining the opinion that this desirable settlement of the problem is in sight may be gathered from the subjoined report abridged from the *Times*:—

Sir Henry Roscoe introduced the deputation, and Prof. Michael Foster, Sir S. Wilks, Sir William MacCormac, Dr. F. Taylor, Lord Reay, Dr. Rendall, the President of Magdalen, Dr. Crosby, Mr. Sidney Webb, Mr. Ralph Palmer, and Sir Wolfe Barry, representing a variety of interests, spoke in support of its object. In the course of his reply, the Duke of Devonshire said:—

I wish, in the first place, to express to you, gentlemen, my cordial thanks for the trouble which you have taken in coming here, for the purpose of repeating and confirming the representations which many of you have, in various other ways, already made as to your sense of the great importance of a reconstitution of the London University upon such lines and principles as will render it, not, perhaps, a teaching University of exactly the same character as the older Universities, but as an institution which will be recognised by all who are competent to form an opinion, and all who hold a leading position in scientific knowledge, as a real and genuine teaching University. The assistance which you have rendered to me in coming in such strength to repeat and confirm these representations will be very great. This deputation was not necessary, so far as the Government was concerned, in order to convince them of the importance of the subject. The fact that the Government has already in two Sessions brought forward a Bill to give effect to the recommendations of the Cowper Commission, has shown that they, at all events, have been convinced by that report of the necessity of such a measure. Neither was the deputation required in order to remove any political obstacles to the passing of such a measure. Politics, I am happy to say, political differences have never entered into this question at all, and a great many members of the present Opposition are as fully committed to the principle of this Bill as the members of the Government themselves. The value of this deputation in my opinion consists in the support which it will give to me in urging upon my colleagues, and which it will give to them in urging upon Parliament, the importance which is attached to the question by almost the whole of those in any way connected with any of the teaching institutions of this great metropolis, and in urging upon them the expediency and the necessity of making such moderate provision of Parliamentary time as may be necessary to remove or overcome the small amount of opposition which still exists as regards the measure. I have, however, little doubt that the more fully I can convince my colleagues of your resolute and determined attitude upon this question, the smaller will be the actual sacrifice of Parliamentary time which will be demanded from them. Much, gentlemen, as the delay which has occurred in dealing with this question is to be regretted, it has, I think, been accompanied by one compensating advantage. It is that the discussion and consideration which have been given to the subject during this period of delay have tended in the direction of removing almost the whole of the serious opposition which has ever been entertained to it. This delay has enabled certain concessions to be made by the advocates of the proposal and a compromise to be arrived at, which has, I believe, substantially removed, as I have said, any serious opposition which had to be encountered. The measure as now proposed cannot be regarded as a triumph of any section of opinion or of interests, but will be, I think, properly and rightly regarded as a fair and just compromise of every shade of opinion upon the University question. Due regard has been paid to the strong and conscientious objections—I will not say whether well-founded objections or not—which were felt by a certain number of gentlemen who undertook the defence of the character and reputation of the work which had already been performed by the existing London University, and the gentlemen who undertook the defence of what they considered to be the interest of external students and those who undertook the defence of independent teaching and the rights of the Convocation of the University. So far has the process of compromise and reconciliation of opinion been carried out, that I have heard that it is possible that the view may be urged that such general agreement has been arrived at that the appointment of a statutory commission is no longer required, and that it would be in the power of the Senate of the University of London itself now to frame such a scheme and ask for the grant of such a charter as would carry out all the objects desired without the interposition of Parliament or the appointment of a Royal Commission. That, perhaps, is a suggestion which has not come under the attention of gentlemen present. I observe that it has received no attention or observation to-day. I am not sufficiently acquainted with the details which will be necessary in order to carry out the report of the Cowper Commission to say whether such a suggestion is possible or not. But it would to some extent strengthen my hands in putting aside a course which may possibly be recommended with some plausibility if, before this deputation separates, I could receive the opinion of some gentlemen who are present. I am under the impression that, although upon vital points practical unanimity has to a great extent been arrived at, the details which would require to be elaborated are probably such that great obstacles would be found to arise in any course except that recommended by the Commission. I should like, however, to receive an expression of opinion that notwithstanding the progress made towards unanimity in this matter, the course recommended by the Commission—the appointment of a statutory commission to frame the future statutes and to reconstitute the University—is the only one to insure the scheme from further delay and perhaps ultimate failure.

Sir H. Roscoe said that the matter had not been formally brought before the Senate, but he should be expressing the view of his colleagues if he said that the question whether this reorganisation was to take place by charter, or, under the recommendation of the Cowper Commission, by a statutory commission had engaged their attention for many years, and that they had come to the conclusion that in consequence of the complexity of the question the difficulty of drawing up in black and white any statement in the form of a charter would be extremely great. The suggestion that the Senate might act under powers as a statutory commission had not been brought before them, and he could say nothing about it. But as between a new charter and a statutory commission the consensus of opinion was in favour of the commission rather than the charter.

Mr. Anstey, as a long-standing member of the Senate and a member of the Cowper Commission, thought that a statutory commission was absolutely essential. The matter had never been presented to the Senate, but the difficulties were insuperable in dealing with the details.

The Duke of Devonshire: The suggestion which may still probably be made is that legislation has become unnecessary when the approach to unanimity is so nearly complete that everything which is required might be done by charter on the motion of the Senate and not under statutory powers. London University under its existing charter possesses powers to alter its statutes and regulations subject to the approval of Convocation, and the suggestion which I understand might be made was that that course might be adopted with a reasonable prospect of success. I understand, however, that Mr. Anstey has expressed the unanimous, or almost unanimous, opinion of those present that that is not the case, and that nothing short of a body armed with statutory powers, such as the proposed commission, would be sufficient.

Sir Joshua Fitch said the question had been amply discussed by the Royal Commission, and their deliverances were unanimous and unanswerable. The difficulty of submitting such a charter to a scattered body like Convocation was too serious for the attempt to be practicable.

Mr. Anstey explained that the unanimity was only on the point that there should be a statutory commission.

After thanking the Duke of Devonshire for his reception of the deputation, the members of it withdrew.

THE FORTHCOMING INTERNATIONAL CONGRESS OF ZOOLOGY.

ENGLISH zoologists ought to learn with satisfaction that the International Congress, which has already met in France, Russia, and Holland, will meet in this country next August. The first Congress took place in Paris at the time of the International Exhibition in 1889. For some reason—perhaps the cholera—the second meeting, held in Moscow in 1892, was not largely attended. The third meeting at Leyden, in 1895, was attended by 173 zoologists with their wives and other members of their families.

It is to be hoped and expected that the meeting at Cambridge will be still more largely attended, and there is every reason to hope that the German element, which has not been conspicuous at previous meetings, will be better represented in this country.

We have already stated that, unfortunately, owing to the condition of his health and his numerous and arduous official duties, Sir William Flower, K.C.B., F.R.S., who was naturally elected President for the fourth Congress at the meeting in Leyden, has felt constrained to resign his post. To the general satisfaction of zoologists the Right Hon. Sir John Lubbock, Bart., F.R.S., was appointed in his place. At Cambridge a strong Committee has been formed, which is now actively engaged making the necessary preparations for the coming together of zoologists, and for their suitable reception and entertainment.

It may be mentioned by the way that August 23 and the town of Cambridge are the date and place of meeting, not only of zoologists, but also of physiologists, who intend to hold a Congress in the same week.

The Executive Committee of the Congress, selected from the General Committee, has somewhat varied the mode of invitation which obtained at previous Congresses. The invitation to the Congress is signed solely by English zoologists, and, on the whole, the list may be said to be a representative one, although it is to be regretted that Mr. A. R. Wallace and Prof. Allman have felt the weight of years too heavy to justify them in taking any part in this Congress. Our fellow zoologists in the Colonies and India have been invited to join the General Committee, and steps are being taken to invite the Indian and Colonial Governments to send delegates to the Congress. The more eminent foreign zoologists have been invited to form the Committee of Patronage which is always established at these Congresses, and we are glad to hear that already more than sixty have agreed to become members of this Committee, and a number have declared their intention of being present at the meeting if they possibly can. Among these may be mentioned Prof. Milne-Edwards (of Paris), Prof. Hubrecht (of Utrecht), and Prof. Kowalevsky (of St. Petersburg).

Visitors to earlier Congresses always brought away an account of generous hospitality, and there can be no doubt that our foreign friends will be charmed at meeting in a place so strange and interesting to them as an English University town. If English zoologists are to keep up the high standard of previous Congresses, from the point of view of hospitality, it will be necessary for them to contribute handsomely to the funds of the Congress. It may be mentioned that Mr. P. L. Sclater, F.R.S., and Prof. Hickson, F.R.S, are the Treasurers for this meeting.

The Zoological Society has placed its house at the disposal of the Executive Committee, and all letters to the Treasurers or the Secretaries should be addressed to them at No. 3 Hanover Square.

We are requested by the Secretaries to say that they have taken every means in their power to send invitations and notices to all zoologists whom they have been able to reach; but Secretaries are not infallible, and the Post Office itself has been known to fail in its duties before now. Any zoologist therefore, whether foreign or English, who has not yet received notices with regard to the Congress, should put himself into communication with the Secretaries at the above address.

MODERN VIEWS OF THE RAINBOW.[1]

DESCARTES'S theory of the rainbow, which is still found in all optical text-books, is hardly even a rough approximation to the true theory. It does not fully explain the ordinary bows, and fails entirely as regards the "spurious bows," improperly so called. Any close observer will, under favourable conditions, notice certain colours on the inside edge of the primary bow which are not consistent with the simple series of spectrum colours demanded by the venerable theory which may be said to mark the birth of modern science. These additional colours, chiefly red and green, recall the colours seen in Newton's rings at some distance from the centre, and at once suggest a similar origin. In a paper on "the intensity of light in the neighbourhood of a caustic" (*Trans. Camb. Phil. Soc.*, 6, 1838, and 8, 1848), Airy has laid the foundation of an adequate theory of the rainbow which is gradually being worked out. With a considerable amount of patience, Mr. J. M. Pernter has calculated the tints and the angular deviations of the rainbow colours for various sizes of rain-drops, and has devised experiments in support of his deductions. A parallel beam of sunlight after reflection and refraction in a spherical rain-drop does not emerge as a parallel beam, or as a bunch of parallel beams of various colours, but as a series of caustics of a somewhat complicated nature, in which the divergence of the colours, and hence their distinctness, separation, or coincidence depend upon the ratio of the radius of the drop to the wave-length of the light. The influence of size is very formidable in the smaller drops, say of 0·01 mm. radius. This would be a very fine spray. The actual size of rain-drops is supposed to vary between 0·1 mm. and 2·6 mm., but the heavy drops of tropical rains are said to attain diameters of 3·4 mm. Their size may be estimated by catching up and weighing a definite number, or by the more difficult method of diffraction. The tables drawn up by Pernter consider drops of twelve different sizes between 0·005 and 1 mm. radius. In order to determine the resulting colours, Pernter selects eight of Maxwell's twenty-two colour equations, which number he finds sufficiently accurate. The first set of his tables state, for a point source of light, the sequence of colours, their composition in terms of red, green, and violet, the relative intensity (admixture of white, after Abney) and position on the colour triangle of each shade for various deviations between 42° 20′ and 36°. These tables are then verified by experiments with cylindrical streams of drops, according to Babinet's method. With 1 mm. drops, Pernter observed red, orange-yellow, green, violet, blue' second violet, and then twenty-four secondaries or spurious colours, chiefly pinkish-violet and green or blue; after the twelfth violet came a whitish band, and then a reversal in the sequence of the colours. The 0·5 mm. drops gave 11 bows with 40 shades. The outer bow and its secondaries were also observed. Verifications in nature are hardly possible, as we cannot measure simultaneously the angles and the size of the drops producing the bow; it is striking, however, that so very few angular measures are extant.

---

[1] See a paper by J. M. Pernter, *Wien. Ber.*, 106, Part 2, [illegible] 1897, and Abstracts of the Physical Society, No. 56.

The white or pale rainbows (fog or mist bows) around moon and sun may appear pale owing to (1) the feeble intensity of the light, (2) the uneven size of the drops, and (3) the mixture of colours. The first cause is probably a real one; the second Pernter is inclined to reject, since the accompanying, often well-defined features such as "glories," Brocken spectra, &c., and also his own tests require homogeneous conditions. As regards the third, Abney has proved that all colours of any shade disappear on being diluted with 75 parts of white, and Pernter's tables show that such cases may well occur. Further, Airy's theory renders white bands possible for all sizes of drops, and necessary for radii below 25 μ. As a stream of water of such fineness cannot be maintained, Pernter produced a mist spray by fixing a 0·5 mm. glass tube in a lead pipe connected with the Innsbruck water mains (pressure 5 atmospheres), and directing the jet against a metallic plate; the size of drops was derived from measurements of diffraction rings. Drops of radius 5 μ gave a yellow margin at 41° 59′, white between 41° 8′ and 38° 27′, and then blue to 37° 41′; larger drops were more difficult to manage. From measurements of fog-bows on Ben Nevis, J. McConnell had in 1890 already calculated the sizes of the respective drops. But some of these observations speak of a red outer margin, for which Pernter looked in vain, and which his calculations do not indicate; Crailheim-Gyllenskiöld (Swedish North Pole expedition, 1882) also describes the margin as of ochre colour. The classical white bows of Bouguer (1744) and of Scoresby (1821), however, do not fit into the theory at all, and were probably due, as the observers remarked, to ice-needles.

The general conclusions are interesting to meteorologists. The greater the drops, the more secondaries (spurious bows). A chief bow of intense pink and green (hardly any blue) indicates drops of diameters ranging from 1 to 2 mm.; intense red always speaks for big drops. Secondaries of green and violet (the blue is masked by contrast) without yellow, immediately joining the chief bow, correspond to drops of 0·5 mm., while five and more secondaries without white and without breaks mark drops of 0·1 mm. A partly white bow is produced by drops of 0·06 mm., and when the drops are still smaller, a real white bow with orange-yellow and blue margins is the result. The net result of these elaborate investigations will be to add a new interest to a natural phenomenon already endowed with many associations of magic and beauty.

EDUARD LINDEMANN AND OSCAR STUMPE.

THE last days of the old year witnessed the removal by death of two astronomers who have rendered valuable services in the respective positions in which they were situated, though not occupying prominent places in the history of the science. Both are mentioned by the authorities under whom they served with the utmost respect, and their loss is acknowledged with profound regret.

Dr. Eduard Lindemann, who died suddenly on December 21, was born in Nishni-Novgorod in 1842, and pursued his scientific studies in the Universities of Kasan and Dorpat. The latter University he left in 1868 to enter the observatory of Pulkova, wherein he filled the office of scientific secretary. In this capacity he had the management of the library, and the preparation of the second part of the "Librorum in Bibliotheca Speculæ Pulkovensis contentorum Catalogus systematicus" was entrusted to him, and very admirably did he fulfil the trust. The duties of his office did not permit him to take a great part in the astronomical observations there carried on; but his tastes led him to take great interest in the Zollner photometer, and the series of careful measures which he made with that instrument have led to his being regarded as an authority in its use. His paper on the "Brilliancy of Bessel's Stars in the Pleiades," published in tome xxxii. of the *Mem. de l'Acad. Imp. des Sci. de S. Petersbourg*, is well known, and he has further used his measures to determine the scale of magnitude employed in the Bonn Durchmusterung.

The second astronomer whose death (at the early age of thirty-five) we have regretfully to mention is Dr. Oscar Stumpe, well known for his contribution on the motion of the solar system. Dr. Stumpe's early life appears to have been one of great hardship and a severe struggle against adverse circumstances. When ten years old he lost his father, but, in face of all difficulties, he determined to win his way to the Berlin University as a student of science. This he accomplished in 1883, though he had had occasionally in previous years to interchange the parts of student and teacher in order to obtain a livelihood and be enabled to continue his career. Even at Berlin, his studies of mathematics and astronomy were interrupted by his duties as a shorthand writer in the Government and Law Courts. From Berlin he went to Bonn, and became a teacher in a private institution. Here he appears to have prepared the heavy calculations which he afterwards incorporated in his inaugural dissertation on the Solar Motion. In this work, Dr. Stumpe based his computations on 1054 stars, whose annual proper motion exceeded 0″·16 in the arc of a great circle. The peculiar feature in the treatment was the introduction of a term depending upon a supposed orbital motion of the stars in the plane of the Milky Way. This term did not appear, however, to have a real existence. The stars were divided into four groups depending upon the amount of the annual proper motion, and the four solutions gave very accordant results in R.A. for the position of the apex of the solar system. The declination appeared less certain, but great confidence has been attached to the results of this particular investigation. Dr. Stumpe's talents as a computer have been generally recognised. He took some share in the calculations of the star places in the Bonn Zone Catalogue under Prof. Deichmuller, and afterwards, on repairing to Berlin in 1891, he was engaged in the preparation of the Zone Catalogue 15°—20° declination. Since that time he has assisted Dr. Auwers in the many researches with which that astronomer has been connected, and who loses in him an able co-operator and a devoted assistant.

NOTES.

AT the ordinary meeting of the Royal Society last week, Sir Nathaniel Lindley, Master of the Rolls, was balloted for and elected a Fellow under the special clause in the statutes which permits the admission of members of the Privy Council; and similarly, to-day it is proposed to ballot for Sir Herbert E. Maxwell. It may be recalled that Sir N. Lindley is a son of the late Dr. John Lindley, the famous botanist.

THE original lists of the subscribers to the Indian Section of the Pasteur International Memorial (British Division) have just been received from Surgeon-Major-General Cleghorn. On glancing down the columns where the profession of the donor is given, the first thing which strikes us is the very varied character of the generous contributors to this fund. We find, for example, members of the Indian Civil Service, the Indian Medical Service, officials in the opium department, in the salt department, forest officers and a number of native forest students, members of the legal profession (including a number of native pleaders), merchants (one of whom mentions having been a patient of Pasteur's), chaplains, medical and other missionaries, numbers of jailors and warders, an indigo planter, locomotive superintendents and assistants, the principal of a theological seminary at Insein in Burma, the superintendent of a Government lunatic asylum, civil apothecaries, bankers, revenue clerks, collectors and magistrates, numbers of "private gentlemen" (Indian), the Governor of Madras, the head-master of a missionary school, &c.; whilst the Army in India has also furnished a large contingent of subscribers. In one district we find a note saying that the inhabitants "are not willing to subscribe to the Pasteur Memorial, but will willingly subscribe towards the Pasteur Institute." The manner in which the fund has been supported in India not only reflects the greatest credit upon the subscribers, but also upon those who have so efficiently organised its collection.

AT the Royal Institution last week, Prof. E. Ray Lankester, F.R.S., in commencing his course of eleven lectures on "The Simplest Living Things," remarked that though of late years it had become the custom to use the term physiology as meaning the study of the chemical and physical properties of living things in contradistinction to the study of their structure, yet fifty years years ago it denoted their general study, and the Fullerian Professorship of Physiology—the chair to which Prof. Lankester has just been appointed—was intended for the furtherance of physiology in the broad sense now given to the term biology. It is proposed in a subsequent course to continue the consideration of the simplest living things by a detailed examination of the structure and activities of the different kinds of qacteria, and to give an outline of the science of bacteriology.

MR. CORNELIUS N. HOAGLAND has given to the Hoagland Biological Laboratory of Brooklyn a mortgage for 24,000 dollars.

ELECTRICITY is to be substituted for steam as the motive power of the elevated railroad system of New York City. Contracts for the new equipment have just been signed.

M. J. O. E. PERRIER, member of the section of anatomy and zoology of the Paris Academy of Sciences, has been elected *membre libre* of the Academy of Medicine, in succession to Dr. Magitot.

THE Council of the Sanitary Institute have accepted an invitation from the Lord Mayor and City Council of Birmingham to hold its seventeenth congress and exhibition in that city in September next.

AFTER sixteen years as professor of geography at the Royal University of Turin, Prof. Guido Cora has resigned his charge, in order to devote himself entirely to scientific researches in geography and related sciences. He has transferred his residence (and the direction of his periodical *Cosmos*) to Rome (Via Goito, 2).

THE death is announced of M. Bazin, the French engineer whose "roller-boat" has on several occasions been referred to in these columns.

THE unpublished manuscripts of the late Prof. Julius Sachs, of Würzburg, have, in accordance with his wish, been placed in the hands of Prof. Noll, of Brünn.

PROF. A. S. KIMBALL, for many years professor of physics in the Worcester Polytechnic Institute, and the author of a number of important papers on the subject of friction between sliding surfaces, as well as of other original contributions to physical science, died on December 2, 1897, after a long illness.

DR. DAWSON WILLIAMS, assistant editor of the *British Medical Journal*, who has been connected with the editorial department of the *Journal* for seventeen years, and has on many occasions discharged the duties of acting editor, has been appointed editor in succession to the late Mr. Ernest Hart. Mr. C. Louis Taylor, who has been sub-editor for the last eleven years, has been appointed assistant editor.

A CURIOUS incident in natural history is related by a correspondent of the *Aberdeen Journal* (January 22). While ferreting rabbits on the bank of a small stream, Mr. J. Robson, a gamekeeper who has for about sixty years been out with rod and gun between the Derwent and the Thurso rivers, states that on the ferret coming out of a hole and running up the edge of the stream, a trout leaped out of the water and fell on the gravel in front of the ferret. The ferret attacked the fish, and after considerable difficulty succeeded in capturing it. Mr. Robson sententiously adds: "I then creeled them both."

THE fifty-first annual general meeting of the Institution of Mechanical Engineers will be held in the rooms of the Institution of Civil Engineers, Westminster, on Thursday and Friday, February 10 and 11. The retiring president, Mr. E. Windsor Richards, will induct into the chair the president-elect, Mr. Samuel W. Johnson. The paper on "Mechanical Features of Electric Traction," by Mr. Philip Dawson, read at the last meeting, will be further discussed, and the following papers will be read and discussed, as far as time permits:—First Report to the Gas Engine Research Committee: description of apparatus and methods and preliminary results, by Prof. F. W. Burstall; steam laundry machinery, by Mr. Sidney Tebbutt.

THE death is announced from Halle of Dr. Ernst Ludwig Taschenberg, well known as an entomologist. Born in 1818, he was appointed in 1856 Director of the Zoological Museum at Halle. His entomological studies, begun after his connection with the Museum, were devoted at first to the hymenopterous fauna of Middle Europe, on which his chief work was "Die Hymenopteren Deutschlands" (1866). These writings were largely compendiums of existing information, and his chief claim to recollection rests on the production of several valuable handbooks on the injurious insects of Germany, such as his "Entomologie für Gärtner und Gartenfreunde" (1871); "Forstwirthschaftliche Insektenkunde" (1874); "Praktische Insektenkunde" (1879-80); and "Die Insekten nach ihrem Schaden und Nutzen" (1882). His "Praktische Insektenkunde," in particular, published in five parts, is an excellent account of the characters, bionomics and economy of all the more important injurious insects of Middle Europe, arranged according to systematic position, and not, as is generally the case, in relation to the nature of the damage they occasion. In the absence of any satisfactory general text-book on the subject published in this country, this work is indispensable to any serious study of injurious insects in Great Britain, as well as in Germany. Save for a single paper on Hymenoptera, which appeared in 1891, Dr. Taschenberg published nothing on entomology during the past fifteen years.

FOR some time past the weather has been unusually mild for the time of year, and the returns received by the Meteorological Office show that higher temperatures have occurred in parts of the British Islands during the past week than in any January during the last twenty-five years at least. At Wick a temperature of 60° was recorded on the 19th, which is 3° higher than any previous record in this month, and in other parts of Scotland almost equally high readings were observed. The *Weekly Weather Report* of the 22nd inst. showed that the temperature was 7° or 8° above the mean in all districts except the north of Scotland, where it was 5° above the average.

THE current-intensity of a lightning flash is difficult to determine, since we cannot well send it through a galvanometer and determine the magnetic field produced by it. But there are other lines along which we can approach the problem, as has recently been indicated by F. Pockels in the jubilee number of *Wiedemann's Annalen*. It has been noticed that some rocks found on the surface of the earth exhibit a magnetisation which is quite out of keeping with the earth's ordinary magnetism. The probability is at once suggested that their magnetisation may be due to lightning discharges in the neighbourhood. Herr Pockels cut some rods out of the basalt of the Winterberg in Saxony which showed such irregular magnetism, and found on testing them that the permanent magnetism they possessed could only be imparted to them by a current of at least 2900 amperes passing along the surface of the rock. If the discharge did not pass there, it must have been a good deal stronger, so that this is only a minimum value. Later on, he cut some basalt in the neighbourhood of a tree which had been damaged by lightning, a circumstance which gave him some clue to the distance at which the current passed. The value then obtained for the current strength of the lightning was 6500 amperes.

M. ARMAND VIRÉ contributes to the *Revue générale des Sciences* for December 30, a highly interesting paper on subterranean fauna, which he has made the subject of extended study, both in the catacombs of Paris and in the large caves of the Jura, the Pyrenees, and the central plateau of France. A number of illustrations are given of the cæcal forms of arthropods and crustacea discovered by M. Viré, several of which have been described as new species, though the author has endeavoured to refer them to existing forms which have become modified by environment. Most of these cave inhabitants are characterised by the extraordinary development of their tactile and auditory organs, their antennæ, legs, and even their bodies being covered with fine hairs highly sensitive to the slightest disturbance. In searching for transitional types, M. Viré has met with a fair measure of success. In the case of *Asellus aquaticus*, both normal and subterranean forms exist, the latter presenting marked differences in their antennules. The author considers that the subterranean genus of beetles, *Anophthalmus*, is probably referable to *Trechus*, and that the new species, *Niphargus virei*, is possibly a modified form of *Gammarus*. Finally, M. Viré suggests the desirability of an extended series of experiments on these transitional forms, with a view of ascertaining how far they tend to revert to the normal types on being restored to light.

THE transformation of Röntgen rays by metals forms the subject of a note contributed to the Société Française de Physique, by M. G. Sagnac (*Bulletin*, No. 106). When such rays are incident on a metal surface they are not perceptibly reflected, but the superficial layer transforms them into secondary rays capable of producing photographic impressions, of exciting fluorescent screens, or of discharging electrification. These secondary rays differ from ordinary Röntgen rays in that they are freely absorbed by aluminium, the absorption giving rise to a further kind of tertiary rays, still more readily absorbed by aluminium. M. Sagnac suggests that the secondary and tertiary rays may be intermediate between true Röntgen and Lénard rays.

AN important memoir on the magnetic properties of tempered steel has been communicated to the Société d'Encouragement pour l'Industrie Nationale, for publication in their *Bulletin*. The authoress, Madame Sklodowska Curie, discusses which are the best kinds of steel for the construction of permanent magnets. In the first series of experiments, bars and occasionally rings of steel were heated in an electric furnace the spiral current of which at the same time furnished the magnetic field. It was found that steel does not take the temper unless heated to a temperature superior to that at which its magnetic properties change. Among various steels, those containing 1·2 per cent. of carbon were found best suited for the construction of permanent magnets. Madame Sklodowska Curie has also considered the presence of different metals in steel. While these do not usually modify the residual magnetisation, they often considerably ncrease the coercitive field, *i.e.* the field required to cause demagnetisation; the addition of tungsten or molybdenum furnishing the best steel for magnets. The paper concludes with an examination of the stability of magnetisation in bars, the effect of blows and of variations of temperature being specially considered. The greater the coercitive field the less is the effect of blows; heating to 200° considerably affects good magnetic steel, even a temperature of 100° is detrimental, while the best permanent magnets are made by heating the steel to only 60° and partially demagnetising it after having magnetised it to the point of saturation.

THE *Journal de Physique* for January contains, in addition to abstracts, papers by M. A. Leduc, on the densities, molecular volumes, compressibility, and dilatation of gases at different temperatures and at mean pressures; by M. H. Pellat, on the variation of energy in isothermal transformations considered with special reference to electric energy; by MM. Pellat and Sacerdote, on contact phenomena; and by M. G. Sagnac, on diffraction of plane waves by slits and gratings.

AN atlas of the currents of the Pacific Ocean has just been published by the Hydrographer of the Admiralty from information collated and prepared in the Meteorological Office. This is the third volume of current charts for the great oceans that has recently been issued in the same way, with the view of providing the navigator with the best available information. The sources from which the observations were obtained being (1) logs received in the Meteorological Office, mainly from the Mercantile Marine, from 1854-96; (2) logs and remark books of H.M. ships from 1830–94. Although charts for each month have been prepared, it has been thought advisable to publish four only, viz. for the representative months January, April, July and October, as the amount of information is still deficient in many places unfrequented by ships. The charts show the average direction of the currents and the maximum and minimum velocity which may be expected. In the case of the Japan Stream, which runs almost uninterruptedly to the north-eastward, the velocity sometimes reaches from seventy to seventy-five miles a day. It is seen that there is generally a south-easterly current down the west coast of North America, and a northerly current along the coast of South America, and that these two streams are deflected near the equator to form the equatorial current.

WE have just received the general report of the operations of the Survey of India Department for the year ending September 30, 1896. The report states that the most interesting and important feature of the year's work is the completion of the telegraphic determination of the difference of longitude between Greenwich and Karachi, undertaken with the view of obtaining a definite value for the longitude of Madras (see p. 284). The tidal observations appear to have been regularly and successfully prosecuted. Self-registering gauges are maintained at thirteen stations, and during the year a new tidal observatory was erected at Suez, while preliminary surveys have been made at Perim, Port Albert Victor, and Porbandar, with the view of adding these places to the list of stations. The error of predicted time of high and low water at those open coast stations which are provided with self-registering gauges did not exceed fifteen minutes in about 65 per cent. of the observed tides, while on about 95 per cent. the predicted height did not differ from the observed by more than eight inches. At the riverain stations, the same amount of accuracy in both time and height was reached in 57 and 60 per cent. respectively, but the time of low water was much less certain than that of high. The bulk of the volume is taken up with details concerning the progress of the various surveys, and the preparation of the results for public use. These surveys, of various kinds, extend over a wide area, and bring home to us the immense amount of work accomplished by the department. Here one may read some details of the delimitation of the frontier between British territory and Afghan, and a few pages further on trace the work of demarcation of the Burma-Siam boundary. The interests of the department are wide enough to embrace, and the machinery sufficiently elastic to produce, either a series of sun pictures or illustrations of the action of cobra poison on the blood.

THE remarkable shark, *Chlamydoselachus anguineus*, whose tricuspid teeth and other structural peculiarities render it unique among recent fishes, has been so rarely obtained that the discovery of a specimen in the Varanger Fjord is a matter of considerable interest. Up to the year 1889 only thirteen specimens of this reanimated Devonian fossil had been secured by naturalists, and all of these came from Japanese waters—the last abode of so many primitive oceanic types. In 1889, however, the Prince of Monaco captured a small *Chlamydoselachus* off Madeira, and now Mr. R. Collett provides a description of an unusually fine and complete specimen caught off the coast of Norway rather more than a year ago. His memoir contains a history of all previous records, and is illustrated by an excellent photograph of the fish taken soon after its capture.

THE reason why spiral growths in nature should sometimes take one direction and sometimes another, is often difficult to determine. Mr. George Wherry recently described a few of these puzzles in nature growth before the Cambridge Medical Society. Referring to shells he pointed out that the ancient whelk, now in fossil form (*Fusus antiquus*) is usually left-handed, while in the present generation of common whelks the shell is always right-handed. Nevertheless, among the right-handed shells there is occasionally found a specimen of a modern whelk of the ancestral type going a contrary curve. What was there at work in the whelk when the soft young creature began life to give it the twist to left or right? and why are the ancient whelks found going the "wrong" way? Similar questions may be asked of other natural torsions. For instance, spiral growth in plant-life is a subject of bewildering interest, and though worked at by so many great observers, from John Hunter to the Darwins and De Candolle and the modern Germans, there are still many phenomena wholly unexplained. The hop and honeysuckle take the form of a left-handed screw; the majority of twining plants, however, twine like a right-handed screw—*i.e.* from the left below to the right above when the plant and its support are looked at from the exterior. A twining plant will make its spiral curves without a support if the terminal be merely steadied by a thread and weight over a pulley so that the apex of the shoot is drawn vertically upwards, but a free horizontally sweeping shoot will make no spiral turns at all. There are also other spiral growths which present many points of interest, and sometimes the value of a twist in a particular direction can be easily understood. Mr. Wherry points out that the horns of the koodoo, for example, are twisted in a right-handed spiral on the left side and a left-handed spiral on the right side. The result is that when the animal rushes through the bush the horns thrown back act as a wedge and drive aside the branches as the koodoo dashes through the thicket. With regard to hoofs and nails, it is astonishing under the influence of moisture and absence of friction how these organs will curve and grow spirally.

THE cause of death by electric shocks has been experimentally investigated by Prof. T. Oliver and Dr. R. A. Bolam, who describe their methods and results in the *British Medical Journal*. The increasing employment of electricity within the last few years has demonstrated, by the accidents to workmen engaged in its generation and distribution, that danger is involved. Two opinions are held as to the cause of death in such cases, viz.: (1) that death is due to failure of the respiratory centre (d'Arsonval); (2) that it is due to sudden arrest of the heart's action. From the appearance presented by the internal organs after death, some physiologists have maintained that death is due to asphyxia. But other evidence suggests that death is not due to failure of the respiratory centre. In the experiments carried out by Prof. Oliver and Dr. Bolam, an alternating current was used, and death appears to have resulted from heart rather than respiratory failure. Whilst in some of the experiments death seemed to be due to contemporaneous cessation of the respiration and heart's action, yet in most there was ample demonstration that the organ first to be arrested was the heart, for breathing was observed to continue rhythmically for a brief period, and then irregularly and feebly before stopping. There is reason to believe that only in the case of very high voltages with currents considerably above the potential usually required to kill the animal is there simultaneous stoppage of heart and respiration. Primary cessation of the heart's beat is, without doubt, the general rule, while under no circumstances did the authors succeed in causing primary arrest of respiration followed by failure of the heart. It follows from this that resuscitation in apparent death from electric shock is made much more difficult than if the fatal result were brought about by respiratory failure. With reference to these experiments, Dr. Lewis Jones calls attention, in the *Electrical Review*, to a similar investigation carried out by him in 1895, using a continuous current.

THE first volume is announced of the new "Flora of the Pyrenees," by the late P. Bubani, edited by Prof. Penzig, of Genoa. It is published by Hoepli, of Milan, and will be followed by three other volumes.

AN amusing instance of the want of observation of the commonest phenomena of nature has come under our notice in a schedule of the "Language of Flowers" issued by a well-known firm of perfumers. The symbol for "assiduous to please" is "sprig of ivy with tendrils"!

DR. A. WAGNER, of Neuhaus am Inn, Bavaria, issues a list of fifty microphotographs at 1 m. and 1 m. 50 each, a reduction on a quantity. The subjects are entirely botanical, and include sections and microscopic organs of Phanerogams and Cryptogams.

DURING February the following science lectures will be given at the Royal Victoria Hall:—February 1, "Insects in a London Back Garden," Mr. F. Enoch. February 8, "The Problem of the Great African Lakes," Mr. J. E. S. Moore. February 15, "Brains," Mr. Hugh de Haviland.

MR. S. B. J. SKERTCHLY has a note, in the "Geological Survey of Queensland," on a plant which he calls the "copper plant," *Polycarpæa spirostyles*, belonging to the Caryophyllaceæ. He finds it always associated with copper lodes, and thinks it may be of use, on this account, from a practical point of view. Analysis shows the ash to contain an appreciable amount of copper.

DR. C. E. BESSEY republishes, in a separate form, his address as retiring president of the Botanical Society of America, entitled "The Phylogeny and Taxonomy of Angiosperms." A modification, to a not very large extent, is proposed of the systems of De Candolle and of Eichler and Prantl, by which it is thought that the phylogenetic relationships of the orders of Monocotyledons and Dicotyledons are more completely indicated.

WE have received the first three numbers of a new serial, the *Circular* of the Royal Botanic Gardens, Ceylon, intended to deal with agricultural, horticultural, and botanical topics, with special reference to the work carried on in the Botanic Garden. The chief subject treated in these numbers is the canker of the cacao tree, its cause, and the possible remedies, including a correspondence on the subject with the authorities at Kew.

MR. J. H. HART, the Superintendent of the Royal Botanic Garden, Trinidad, has commenced, in the *Bulletin of Miscellaneous Information*, the publication of a monograph of the Ferns of the British West Indies and Guiana, prepared by Mr. G. S. Jenman. Vol. iv. part 5 of the *Bulletin*, for January 1898, is entirely occupied by the two genera *Hymenophyllum* and *Trichomanes*, twenty-nine species being described of the former, and forty-two of the latter genus.

A LEAFLET on "The Advantages of Boiling Drinking Water and Milk" has just been published by the National Health Society. It is written by Mrs. Percy Frankland, and is intended for distribution amongst both rich and poor. It contains a brief account of the dangers which may attend the use of contaminated water and milk, and a few simple instructions are given for ensuring the removal of any noxious germs which may be present by the efficient boiling of these liquids. Copies for distribution may be obtained of the Secretary of the Society, 53 Berners Street, London, W.

THE additions to the Zoological Society's Gardens during the past week include a Mozambique Monkey (*Cercopithecus pygerythrus*) from South-East Africa, presented by Miss Rogers; a Smooth-headed Capuchin (*Cebus monachus*) from South-east Brazil, presented by Mr. W. S. Jay; a Chinese Goose (*Anser cygnoides*) from China, presented by the Rev. E. Hensley; a Beccari's Cassowary (*Casuarius beccarii*) from New Guinea, deposited.

IN the notice of Mr. Dodgson, the words "symbolically developing and popularising" should be inserted before "the study" in the seventh line from the end (p. 280).

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN FEBRUARY:—

Feb. 3. 18h. 43m. to 19h. 10m. δ Geminorum (mag. 3·7) occulted by the moon.
5. 17h. 34m. Near approach of o′ Cancri to the moon.
6. Pallas 1° N. of τ Eridani.
9. 10h. 13m. Minimum of β Persei (Algol).
11. 6h. Mercury 1′ N. of Mars.
11. 17h. 26m. to 17h. 54m. 89 Virginis (mag. 5·2) occulted by the moon.
12. 7h. 2m. Minimum of β Persei (Algol).
13. 19h. 33m. to 20h. 37m. *b* Scorpii (mag. 4·8) occulted by the moon.
14. 10h. 23m. Moon in conjunction with α Scorpii (Antares).
14. Illuminated portion of Venus = 1·000.
,, ,, Mars = 0·981.
14. 17h. Saturn in conjunction with moon. Saturn 5° 30′ N.
15. Venus 1½° S. of the sun.
23. 8h. 52m. to 9h. 11m. Jupiter with only one visible satellite.

THEORY OF PERIODIC COMETS.—We have already called attention in this column (September 16, p. 473) to the recent work of M. Callandreau on the subject of disaggregation of cometary matter, and pointed out the lines he has followed in his research. In the *Annales de l'Observatoire de Paris, Memoires*, t. xxiii., he has collected the results of his recent work, and examined to what extent the theory is supported by recent observations. The circumstances favourable for disruption are—close approach to Jupiter, small relative velocity, and small excentricity of orbit. The question is, therefore, to what extent do the elements of comets which have given evidence of disintegration exhibit these peculiarities. It must be remembered, that it is only since the comet of 1882 was seen to be accompanied by faint nebulous matter that the neighbourhood of a comet has been regularly explored to detect the presence of companions. The most typical case yet noticed is that of the comet of 1889 V., which was very numerously attended, and of which it has been established that the orbit of at least one of the companions cuts the orbit of the principal comet near its aphelion. Since this comet, as Chandler has shown, made an approach to Jupiter in 1886, it seems likely that the disruption took place then, owing to the influence of that planet, since the conditions indicated as favourable to the theory are all present in this instance. The existence of the two distinct comets of Wolf and Barnard (1892 V.) can with probability be traced to the action of Jupiter, but the epoch at which the approach to the planet occurred cannot be decided.

The famous instance of Biela is inconclusive. A general investigation of the distance between the two nuclei shows that this is greatest about perihelion, and least at, or near, aphelion. The difficulty of identifying the two nuclei led Prof. Hubbard to make two hypotheses in his calculations, and he preferred that which gave the minimum distance between the two nuclei. But M. Callandreau shows that adopting the second hypothesis, which, though rejected by Hubbard, is by no means excluded by the result of his researches, the division of the comet into two parts would take place in Heliocentric Longitude 266°, while the longitude of the point of closest approach of the orbit of Jupiter and the comet is 268°.

The suggestion that a family of comets with aphelia near the orbit of Jupiter and with periods approximately half that of the planet, should be introduced into the solar system by the action of Jupiter, is not without its objections, based on the theory of probabilities; but the multiplication of comets by disruption is free from this objection, and would also tend to explain the faintness which is a feature of this class of comets.

PHOTOGRAPHIC MAGNITUDES.—In *Circular* No. 22, issued from the Harvard College Observatory by Prof. Pickering, the question of photographic magnitudes of stars is considered. It is pointed out that it is a matter of great importance to know how much the relative brightness of star images will vary on different plates, or on different portions of the same plate. It is especially important to determine the amount of this error, since it is not easily eliminated and has been supposed to be large by some persons not familiar with stellar photographs. A moment's investigation of photographs of the same portion of the sky shows that this source of error is small, so small that it is not readily determined by direct measurement. The uniformity of different portions of the film is shown by allowing the stars to trail over the plate. A much more delicate test was found in the discussion of a series of measures of the variables discovered by Prof. Bailey in the cluster Messier 5. Sixty-three of these variables were compared on 41 plates by Argelander's method, with a sequence of comparison stars. Estimates were made of the difference in grades of each variable from the next brighter and the next fainter star of the sequence. The sum of these differences gives the interval between the comparison stars, and combining all the results gives, in general, several measures of each interval on each plate. Each comparison star in turn may then be regarded as a variable, and its changes in light determined from the next brighter and next fainter star of the sequence. Comparatively few measures were made of the six brightest and the three faintest stars of the sequence. The five intermediate stars were measured on 41, 39, 38, 30 and 30 photographs respectively. On the average, therefore, five stars were measured on 35 plates, which gave a range of 0·12 magnitudes and an average deviation of 0·02 magnitudes. The average deviation 0·02 includes: (1) the errors of observation; (2) errors due to neglecting hundredths of a magnitude; (3) errors due to irregularities in the film which enter with their full value into the result. Since the combined effect of these three sources of error is only ± 0·02, it is evident that neither of them can be large. The errors due to the film are in fact so small, that there is no evidence that they exist, and more delicate methods of measurements are required to render them perceptible.

THE COMPARATIVE PHYSIOLOGY OF THE SUPRARENAL CAPSULES.[1]

DR. SWALE VINCENT has in previous communications given certain experimental evidence in favour of the view that the paired suprarenal bodies and the inter-renal gland of Elasmobranch fishes correspond respectively to the medulla and the cortex of the suprarenal capsules of the higher Vertebrata. This evidence consisted in the utilisation of the discovery of Oliver and Schäfer that the medulla of mammalian suprarenal contained a substance which, when injected into the circulation, produced an enormous rise of blood-pressure. Dr. Vincent found that the paired bodies of Elasmobranchs contained this active substance, while the inter-renal gland in the same order of fishes and the known suprarenals of Teleosts did not. Thus it appeared that the medullary portion of the suprarenal was absent in Teleosts, the suprarenal bodies in this order of fishes consisting solely of cortex.

Since performing the above experiments his attention has been given to the general physiological effects of extracts obtained from suprarenal capsules. The extracts were made separately from cortex and medulla, and injected subcutaneously into various mammals. It was noted that the injection of medullary material was invariably fatal if a sufficiently large dose were administered, while the cortical extracts produced no appreciable physiological effects. The mode of preparing the extracts was usually by boiling for a short time in water or normal saline, and carefully filtering, as it had been found that boiling. if not too prolonged, did not destroy the active material. The symptoms usually observed were a characteristic progressive paralysis, with occasionally convulsions. Death probably occurred by respiratory paralysis.

Since these effects were only produced by medullary substance, there appeared now to be afforded a still further means of testing the above views concerning the homologies of the two kinds of suprarenal in Elasmobranchs and the corpuscles of Stannius in Teleosts with the two portions of the suprarenal capsules of the higher Vertebrata. Accordingly, in the present communication the hypothesis has been established on a still firmer basis by testing the effects of the two kinds of gland in Elasmobranchs and of the cortical suprarenals of Teleosts, where extracts of them are injected subcutaneously into small mammals. Naturally only very small quantities of material have been available for this purpose, but the effects upon mice have been quite definite. Material from *Gadus morrhua* produced no effects whatever. The paired bodies from *Scyllium canicula* and *Raja clavata* produced characteristic symptoms and a rapidly fatal result. Again, the inter-renal from these genera was found to be inactive. One of the mice certainly which was injected with an inter-renal extract was found dead on the following day, but Dr. Vincent thinks this result can reasonably be attributed to contamination with the paired bodies, and is analogous to the effect one sometimes obtains upon the blood-pressure when inter-renal extract is injected intravenously. The symptoms noted in the mice as the result of injection of the active material were quickened respiration at first, which afterwards became slower and slower, and paralysis commencing in the hind-limbs, and finally affecting the whole body. In one case there were convulsions. In fact, the results were typically those of poisoning by suprarenal medulla.

These experiments afford further positive evidence of the homology of the paired bodies of Elasmobranchs with the medulla of the mammalian suprarenal. The direct evidence in favour of the homology of the inter-renal with the cortex of the suprarenal is mostly morphological and histological, and this the author has detailed elsewhere.

---

[1] Abstract of a paper entitled "Further Observations upon the Comparative Physiology of the Suprarenal Capsules." By Dr. Swale Vincent. (Read before the Royal Society, November 25, 1897.

MIMICRY IN INSECTS.[1]

SHARING in the perplexity avowedly felt by many of my predecessors in this chair as to the choice of a subject for the annual address—perplexity arising rather from the redundancy than from the scarcity of entomological matter—I have been led to think, considering the wide-reaching importance of the questions involved and the unmistakeable interest shown in the recent discussion at two of our meetings, that some account of the mimetic relations existing among insects might not be out of place. Having for a considerable period devoted some attention to the matter, I propose to pass in review what has been placed on record; and if, in so doing, I traverse ground very familiar to most of us, my excuse must be the fascinating interest which attaches to the whole subject.

EARLY CONTRIBUTIONS TO MIMICRY.

The application by Henry Walter Bates, our lamented President, of the great principle of natural selection in elucidation of the mimicries found among insects is too well known to require any detailed repetition here. It is sufficient to recall that, as the result of many years' experience in tropical South America, Bates established the facts that (1) among the abundant and conspicuous butterflies of the groups Danainæ, Heliconiinæ, Acræinæ, and some Papilioninæ were found very much rarer mimicing forms, chiefly of the group Pierinæ but partly belonging to other groups and some even to the Heterocera, which, departing very widely from the aspect of their respective allies, imitated with more or less exactness the abundant species in question; (2) the numerous and showy Danainæ, &c., although of slow flight, did not appear to be molested by the usual insectivorous foes; and (3) the members of these unassailed tribes possessed malodorous juices not found in the mimicking forms or their allies. From these data he argued that the explanation of these extraordinary resemblances was to be found in the great advantage it would be to species undefended by offensive secretions, and therefore palatable and much hunted down, to find escape in the disguise of species recognised and avoided as unpalatable; and traced the mimicries to the long-continued action of natural selection, perpetually weeding out by insectivorous agencies every occurring variation not in the direction of likeness to the protected forms, but as perpetually preserving, and so aiding the development by heredity of, every variation favourable to the attainment of the protective mimicry.

This sagacious application of the Darwinian theory in solution of one of the most difficult and baffling of the problems presented to zoologists, was of the greatest service and encouragement to all students of evolution. I retain to-day the liveliest recollection of the delight I experienced in the perusal of a copy of Bates's memoir received from himself; for his work was not that of the mere cabinet systematist, but came with all the force of face-to-face commune with the abounding life of the tropics.

Before two years had passed, Bates's explanation of mimicry was confirmed by his former companion in exploration, Alfred Russel Wallace, who, working with equal devotion in the

---

[1] Abstract of the presidential address delivered before the Entomological Society of London on January 19, by Mr. Roland Trimen, F.R.S.

Malayan Islands, had observed and was able to adduce a strictly analogous series of mimetic resemblances among Oriental butterflies, and gave his unreserved acceptance of the Batesian interpretation. Such support from the co-founder with Darwin of the theory of natural selection, and from a naturalist of the widest experience in both Western and Eastern tropics, was of the greatest weight with evolutionists generally.

My own contribution to the subject was read to the Linnean Society in March 1868. In the previous year I had made an entomological tour in Natal, and had enjoyed some precious opportunities of observing in nature several cases of mimicry between species not inhabiting the Cape Colony. There was no claim to originality in my paper; it simply rounded off the case by adding from Africa, the third great tropical region of the globe, a series of instances and observed facts confirmatory of those brought forward by Bates from the Neotropical, and by Wallace from the Oriental region. Of course I had had nothing like the extended field experiences of those great naturalists, and the African material then available was but scanty; but it so happened that perhaps the most striking and elaborate of all recorded cases of mimicry—that exhibited by the females of the *Merope*-group of *Papilio*—had come under my personal observation in South Africa, and I was thus in a position to describe satisfactorily a wonderful illustration of the Batesian theory.[1]

It will be remembered that Bates, in his memorable paper, also brought to notice the very close resemblances, or apparent mimicries, which unquestionably exist between species belonging to different groups or subfamilies of protected distasteful butterflies themselves; but neither he nor Wallace felt able to give any explanation of these instances, which obviously differed very materially from the cases of mimicry of an unpalatable protected species by a palatable unprotected one. Not until 1879 was there any elucidation of this side of the matter, but in May of that year appeared in *Kosmos*, Fritz Müller's notable paper on "*Ituna* and *Thyridia*," which was translated by Prof. Meldola, and printed in our *Proceedings* for the same year (p. xx.). In this memoir, Müller made the valuable suggestion that the advantage derivable from these resemblances between protected forms was the division between two species of the percentage of victims to the inexperience of young insectivorous enemies which every separate species, however well protected by distastefulness, must pay.

Prof. Meldola not only brought forward and supported, with all his wonted grasp and acumen, F. Müller's daring interpretation of this phenomenon, but in 1882, in a paper discussing the objections brought against Müller's view, made a distinct advance by showing how that view could justly be extended to explain the characteristic and peculiar prevalence of one type of colouring and marking throughout large numbers of species in protected groups—so especially noticeable in the sub-families Danainæ, Heliconiinæ, and Acræinæ.

In 1887 was published Prof. Poulton's most interesting memoir entitled "The Experimental Proof of the Protective Value of Colours and Markings in Insects in reference to their Vertebrate Enemies," which dealt in great detail with the actual results of numerous experiments conducted by himself and other naturalists with the object of ascertaining to what extent highly conspicuous (almost always distasteful) larvæ and perfect insects are rejected or eaten by birds, lizards and frogs. The conclusions given at the close of this paper cover a wide range in connection with the subject of warning coloration, and among them I would call special attention to No. 5, in which the author points out that "In the various species in which a conspicuous appearance is produced by colour and marking, the same colours and patterns appear again and again repeated," and adds that "In this way the vertebrate enemies are only compelled to learn a few types of appearance, and the types themselves are of a kind which such enemies most easily learn." This generalisation certainly had the merit of first detecting a great additional advantage derivable from the common aspect exhibited by a number of protected forms in the extended "Müllerian" associations indicated by Prof. Meldola; and it was applied by Wallace to the case of the Heliconiidæ in the comprehensive survey of warning coloration and mimicry generally given in "Darwinism." We are further indebted to Prof. Poulton for the discussion and summary of all extant data up to 1890 in his "Colours of Animals"— a work which abounds in pregnant suggestion, and indicates with justice and clearness how far the evidence forthcoming was valid, and in what directions evidence still lacking should be sought.

Wallace well observed that "to set forth adequately the varied and surprising facts of mimicry would need a large and copiously illustrated volume; and no more interesting subject could be taken up by a naturalist who has access to our great collections and can devote the necessary time to search out the many examples of mimicry that lie hidden in our museums." A work ostensibly of this character was issued in 1892–93, in two parts, from the pen of the late Dr. Erich Haase, under the title of "Untersuchungen über die Mimicry auf Grundlage eines natürlichen Systems der Papilioniden"; and last year an English translation of the second part was published, and has quite recently been reviewed by Prof. Poulton (NATURE, November 4 and 11, 1897).

RECENT CONTRIBUTIONS TO THE SUBJECT.

Among recent contributions to the subject, we shall, I think, all agree in assigning a high place to the memoirs with which Dr. F. A. Dixey has enriched our *Transactions*. In 1894 he read before the Society his elaborate paper "On the Phylogeny of the Pierinæ, as illustrated by their Wing-markings and Geographical Distribution," and took occasion to discuss the wide divergence from the primitive or typical pattern of the group caused by mimicry in such genera as *Euterpe*, *Pereute*, *Dismorphia*, &c. Adopting the Müllerian interpretation as expanded by Meldola, he proceeded to offer the original suggestion that, in the acquisition of closer resemblance between two or more protected forms, it was not necessary that in every instance the process of adaptation should lie solely in the imitation of one particular form as model, but that there might very well exist *mutual* convergence of the forms concerned, thus accelerating the attainment of the common beneficial resemblance. This "reciprocal mimicry" the author further explained in a paper read in 1896 "On the Relation of Mimetic Patterns to the Original Form" (pp. 72–75), by a consideration of certain mimetic sets of Heliconii, Pierinæ, and Papilioninæ which present features and relations of pattern and colouring explicable apparently in no other way than by the hypothesis in question. This paper also gave a lucid demonstration, traced through corresponding series of existing forms of both mimetic and non-mimetic Pierinæ, of "the successive steps through which a complicated and practically perfect mimetic pattern could be evolved in simple and easy stages from a form presenting merely the ordinary aspect of its own genus," and further adduced reasons for holding that "it is not necessary that the forms between which mimicry originates should possess considerable initial resemblance." In his latest memoir, "Mimetic Attraction," read on May 5 last, Dr. Dixey expanded a suggestion he had previously (1896) made respecting divergent members of an inedible group to point out—still from evidence in the Pierine subfamily to which he has devoted so much fruitful study—"how the process of gradual assimilation starting from one given point may take not one direction only but several divergent paths at the same time," with the result that a more or less intimate mimetic relation was brought about with several protected forms of quite different affinities, though each connected in their colouring and aspect with some group of distasteful associates. He further set forth very fully the distinction which exists between the mimicry of inedible by edible forms, which could only be in one direction and was of advantage to the mimicker alone, and the assimilation among inedible forms themselves, where the mimetic attraction acts reciprocally, to the advantage of all participators.

Another of our Fellows, Colonel C. Swinhoe, distinguished for his wide and intimate knowledge of Oriental Lepidoptera, read before the Linnean Society, in 1895, a most interesting paper "On Mimicry in Butterflies of the genus *Hypolimnas*." In this memoir, as the author points out, a small group of wide-ranging mimetic insects is followed throughout its geographical distribution; and the process of mimetic modification is traced through the female, from the amazing instability of that sex of *H. bolina* (local form) in the Fiji Islands, where the male is stable and of the normal ancestral pattern and colouring, to the opposite extreme in Africa, where (with the exception of *H. misippus*) both sexes of the known allied forms of the genus are equally mimetic.[1] The singular contrast between the numerous modifications of the female of the *Bolina* type, and the absolutely constant imitation of *Danais chrysippus* alone by the ♀ *H. misippus* is well brought out, and the different courses thus pursued by the respective females are shown to depend on the range, variation, and abundance of the model that is mimicked. Colonel Swinhoe had previously (1887) published a good account of mimicry in Indian butterflies, and in it made special reference to the remarkable series of close likenesses between species belonging to different subgenera of the great protected genus *Euplœa.*

---

[1] At various subsequent dates I was enabled, through the valuable aid of Mr. J. P. Mansel Weale and Colonel J. H. Bowker, to make known to science conclusive evidence of the species-identity of the three mimetic females of *Papilio cenea*, and of the pairing of the widely-differing sexes of that species.

MIMICRY IN VARIOUS ORDERS OF INSECTS.

So much prominence has naturally been given to the very conspicuous development of mimicry among the Lepidoptera, that it is not uncommon to hear the matter spoken of as if limited to butterflies and moths, and even entomologists need to be reminded of the prevalence of the phenomenon among other orders of insects. The stinging *Hymenoptera* furnish the most numerous models to members of other orders, being closely mimicked by numerous Diptera, by many heterocerous Lepidoptera, by various Carabid, Heteromerous, and Longicorn Coleoptera, and by some Hemiptera; while certain ants are well imitated by spiders. As regards *Coleoptera*, mimicry is mainly found within the limits of the order itself—*e.g.* Cicindelids by Heteromera and Longicorns, Carabids by Heteromera, Malacoderms by Longicorns, and Rhynchophora by Longicorns; but certain Cicindelid and Rhynchophorous beetles are closely copied by Orthoptera, belonging respectively to the genera *Condylodeira* and *Scepastus. Lepidoptera* do not seem to find mimickers beyond their own order, unless the case quoted by Haase from E. Hartert, of the resemblance of a large Cicada to the Indian *Thaumantis aliris* (Morphinæ) be one of actual mimicry. Nor do *Diptera* appear to be models for imitation, except in the case of the hunting spiders, which mimic the Muscidæ they chase; although the neuropterous *Bittacus* certainly bears a strong likeness to Tipula, and may possibly find the advantage of that harmless aspect in approaching its prey. It cannot be denied that some of the inter-ordinal mimicries are even more impressive and striking than those so notable among butterflies, the excellence of the superficial disguise of general outline, proportion of parts, colouring, and markings being so great as to throw into obscurity the really vast structural discrepancies. Such cases as the imitation of the South American wasps of the genera *Polybia* and *Synœca* by moths of the genera *Sphecosoma* and *Myrmecopsis*, of the Bornean sand-wasp *Mygnimia aviculus*, by the beetle *Coloborrhombus fasciatipennis*,[2] or of the Philippine tiger-beetle *Tricondyla*, by the cricket *Condylodeira*, are absolute marvels of deception, all belonging to that special phase of mimicry where the obvious advantage to the unarmed mimic lies in being mistaken for the armed and formidable model.

Returning to the general aspects of the subject, it is of importance to consider more closely how the evidence stands in relation to (*a*) persecution by insectivorous foes, (*b*) possession of malodorous and distasteful juices by certain groups of insects, (*c*) rejection or avoidance by foes of the insects provided with offensive juices, and (*d*) loss occasioned to distasteful species by the attacks of young and inexperienced enemies; for it is admittedly on the co-operation of these factors that the theory of mimicry depends.

(*a*) PERSECUTION BY INSECTIVOROUS FOES.

As regards the first point, the broad fact of insects generally constituting the food of countless devourers, vertebrate and invertebrate, is beyond dispute; immense and incessant persecution is universally at work. But when we proceed to examine this world-wide persecution more in detail, and to ask in what special directions it works, or what groups or species are the particular prey of certain groups or species of enemies, we very soon discover how little is exactly known. Birds, for instance, are such notorious and apparently indiscriminate insect-eaters, and some of them are so active and demonstrative in their hunting, that it seems but reasonable to regard them as the chief pursuers on the wing of the abundant and defenceless butterflies. Yet in the discussion which followed the reading of Dr. Dixey's last paper already referred to nothing was more noticeable than the very scanty testimony to such persecution on the part of birds that could be brought forward by the very competent well-travelled entomologists present. In fact, the poverty of observed cases of such attack has induced the opinion among some entomologists that birds very rarely chase butterflies at all, and the published expression of this view by Pryer, Skertchley, Piepers, and other experienced collectors cannot be overlooked. But I am persuaded that in this instance, as in so many others where the life-history of animals is concerned, the dearth of evidence is due to the neglect of well-directed and sustained observation. Little can be gained by merely noting such cases as happen to force themselves on the collector's attention; the collector must resolutely set himself to search out and keep watch upon what really takes place. Considering that there is no record of any naturalist's having seriously taken up the investigation of this matter in the field, I think that very much positive evidence could hardly be expected, and that what has been published goes far in the direction of proving that birds must still be reckoned among the principal enemies of butterflies.

(*b*) POSSESSION OF MALODOROUS AND DISTASTEFUL JUICES BY CERTAIN INSECTS.

The presence of malodorous juices in many insects is a matter of common observation, and is a protective property possessed by several entire groups, especially among the Lepidoptera and Coleoptera. There is abundant evidence as to the prevalence of these secretions, and among the Lepidoptera they are particularly developed in the butterflies of the groups Danainæ, Neotropinæ, Acræinæ, and Heliconinæ, and also in some Papilioninæ, as well as in many moths of the groups Agaristidæ, Chalcosiidæ, Arctiidæ, Lithosiidæ, &c. The strength of the disagreeable odour emitted is in some species very great; Seitz, for instance, mentioning that the smell of the South-American *Heliconius besckei* and *Eueides aliphera* extends over a radius of several paces, and Woodmason and De Nicéville testifying to the same effect as regards the Indian *Papilio philoxenus* and allied forms. When molested many of these offensively-smelling species exude drops of a yellow or whitish fluid which leave on anything they touch a stain and odour difficult to remove, as I have experienced in the case of the Mauritian *Euplœa euphone*, the South-African Danainæ and Acræinæ, and various South-African Agaristidæ, Glaucopidæ, and Arctiidæ.

The origin and manner of acquisition of these unsavoury secretions have yet to be discovered; the suggestion (so much insisted on by Haase) that these juices are directly derived from those of similar quality in the food-plants of the larvæ arising from the long-known circumstance that some of the food-plants of species in the protected groups are of an acrid or poisonous character, such as (*e.g.*) Asclepiads in the case of many Danainæ, and Aristolochia in that of the inedible forms of Papilioninæ. No doubt, too, the fact that the unpleasant qualities are very often fully developed in the larvæ of the distasteful species—as I have found with *Danais chrysippus* and various Acræinæ—lends some weight to the suggestion; but at present nothing approaching sufficient data can be brought forward respecting the actual food plants to which the protected groups, in contrast to the unprotected, are thought to be restricted. It cannot be gainsaid, as Prof. Poulton has pointed out (*Proc. Zool. Soc. Lond.*, 1887, pp. 198, &c., and NATURE, November 4, 1897, p. 3), that the food-plants of many of the distasteful European moths do not belong to any poisonous or acrid category; and his own and Mr. Latter's papers on *Dicranura vinula* alone amply demonstrate what powerful acids can be elaborated by a larva which finds its food in such innocuous plants as poplar and willow. The supposed direct derivation of the nauseous juices from the plants consumed is thus plainly a matter that awaits investigation from both biological and chemical standpoints.

(*c*) AVOIDANCE OR REJECTION OF INSECTS BY INSECTIVOROUS ANIMALS.

The avoidance or rejection as food by insectivorous animals of the insects possessing malodorous or distasteful juices no longer rests merely on the negative evidence given by Bates, Wallace, Belt, and other competent observers, to the effect that in nature such distasteful forms are habitually neglected and unmolested; there is now much positive experimental evidence as to the manifest avoidance or disgust with which such species are left untouched, or thrown aside after tasting, when offered to domesticated or captive vertebrate animals that devour ordinary insects with avidity. The numerous experiments of this kind recorded by Butler, Jenner Weir, Weismann, Poulton, and Lloyd-Morgan, as regards both larvæ and imagos of European species, are supported by a few made by Belt with Heliconiinæ in Central America, by D'Urban and myself with Danainæ and Acræinæ in South Africa, and by Haase with Danainæ in Singapore.

---

[1] It should be noted that in the African *H. salmacis* and the Malagasy *H. dexithea* the sexes are alike and non-mimetic, and that therefore these species probably most closely approximate to the primitive appearance of the genus.

[2] See Pryer, *Trans. Ent. Soc.*, 1885, p. 369, pl. x., who in the same place also figures another most striking case from Borneo, in which the hymenopterous *Triscolia patricialis* is mimicked by the lepidopterous *Scoliomima insignis.*

It is manifest, of course, that even the most distasteful forms cannot enjoy complete immunity from persecution; in ordinary circumstances they are doubtless mainly kept down by parasitic insects, and during any scarcity of more palatable prey it is certain that they will be devoured *faute de mieux* by vertebrates and invertebrates alike.

(*d*) Losses due to Inexperience of Enemies.

As regards the important point whether the protected forms have to suffer a certain percentage of loss from the attacks of young and inexperienced birds and other animals, it must be admitted that the evidence at present forthcoming is exceedingly scanty; and I have long felt considerable doubt as to the sufficiency of this factor to account for the mimetic resemblances, often remarkably close, between members of associated protective groups. But on reviewing carefully the recorded observations which appear to bear on the question, I have found reason to think that there is enough support to justify the provisional acceptance of the Müllerian explanation. We have in the first place Fritz Müller's own capture of Heliconii and Acræinæ with a notched piece bitten out of the wings, and Distant's (*l.c.*, p. 65) of a *Danais chrysippus* whose wings had been bitten unsymmetrically, apparently by a bird. Then there is the significant record of Skertchley, who, among twenty-three species of Bornean butterflies taken with both hindwings mutilated in the same manner, notes no less than four Danainæ, viz. *Hestia lynceus*, *H. leuconoe*, *Ideopsis daos*, and *Euplœa midamus*. Moreover, it is very remarkable that several of those entomologists who have specially emphasised the small part played by birds in attacking butterflies mention, among the few cases of such attack as they witnessed, instances of protected forms being assailed, Sir G. Hampson remarking that in South India the Euplœæ and Danaids were caught as often as any others, and M. Piepers that in two of the four cases which he had seen in Sumatra and Java, the species seized were Euplœæ.

The question underlying this is manifestly whether insect-eating animals have an instinctive inherited discernment of what species are unfit for food, or whether, on the contrary, each individual has to acquire this necessary knowledge by personal experience, aided in some vertebrate groups by parental guidance. So numerous and so marvellous are the instinctive or congenital activities of animals—especially in the insect world, where past experience or parental instruction is almost always non-existent—that there has been a very general disposition on the part of naturalists to incline to the former view in a matter so all-important as suitable food. Yet, as far as experiment has hitherto gone in this direction, there seems good ground for holding that—at any rate in such specially insectivorous vertebrate groups as birds, lizards, and frogs—the young possess no such hereditary faculty of discrimination, but have to discover individually what to avoid. This appears not only from Mr. Jenner Weir's and especially Prof. Poulton's careful and often-repeated experiments with lizards and frogs, but also from Prof. Lloyd-Morgan's study of newly-hatched birds of different orders, which indicates clearly with what complete want of discrimination every object of suitable size is at first pecked at and tasted, but how soon experience tells and is acted upon. Prof. Lloyd-Morgan made special trial of these young birds with many distasteful insects and their larvæ, and states in conclusion that he did not find a single instance of instinctive avoidance, but that the result of his observations is that "in the absence of parental guidance, the young birds have to learn for themselves what is good to eat and what is distasteful, and have no instinctive aversions."

In concluding what I feel to be a very incomplete outline of what has been done in this most important branch of zoological research, I cannot refrain from expressing the gratification I find in noting how by far the chief part in the investigations pursued and in the deductions derived from them has from the outset been borne by Fellows of this Society. It is work on which we may with justice be congratulated, and which should encourage perseverance in the same and kindred lines of inquiry.

Need of Observations of Living Organisms.

Here, as in many other biological researches, it cannot be too strongly insisted on that no result of lasting value can be hoped for without resort to the living animals among all the natural conditions and surroundings. It was not a stay-at-home theorist, familiar only with the dried specimens of the cabinet, that detected the meaning of mimicry and gave to science a rational explanation of the mystery, but an ardent explorer and naturalist, who devoted many of the best years of his life to field-work in tropical lands. I am the last to undervalue the knowledge of the systematist, which is absolutely indispensable to all intelligible record, and I fully recognise that no naturalist can be properly equipped for his work without a fair amount of systematic training; but philosophical discovery in any direction such as we are now considering can never be truly advanced without unflagging observation and experiment among organisms living in their natural environment. How but by the closest and most exact attention to the entire life-history of animals in their native haunts can we expect to deal satisfactorily with such questions as this of mimicry, of protective resemblances generally, of seasonal dimorphism, sexual selection, local variation, and the like? Admitting gratefully the good work of this kind which has been carried on in Europe, and especially in our own country, one cannot but regret that from tropical regions, where alone the abundance, complexity, and incessant activity of life afford full prospect of the adequate reward of such research, we have little more than isolated notes and unconnected and incomplete observations, mere indications—precious as they are—of the rich harvest that lies unreaped for lack of resident workers devoted to the task.

It is on this account that I earnestly renew the plea put forward from this chair on May 5 last, for the establishment, in tropical countries, of biological stations for the study of the terrestrial fauna; where, as in the existing marine biological stations, naturalists could follow, during a succession of seasons, special lines of observation and experiment under favourable conditions of laboratory and other equipment, free from the hindrances and distractions of ordinary collecting travel, and with all the advantages of mutual help and encouragement. The living expenses, for men of the simple tastes of the naturalist, would not be great; and I feel certain that, with the increasing facilities for swift transport, it would not be long before many students of biology would embrace the opportunity so provided for the effectual prosecution of researches of the utmost value to science.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—The usual courses in the Scientific and Medical Departments are being continued this term. Prof. Ray Lankester is lecturing on the "Structure and Classification of Fishes," and Prof. E. B. Poulton on the "Natural History and Classification of Insects." Prof. Tylor purposes to lecture on "Ancient and Barbaric Stages of Culture compared with Advanced Civilisation." The Regius Professor of Medicine (Prof. J. Burdon-Sanderson) proposes to continue his Pathological Lectures of last term by discussing the "Nature and Causes of Tuberculosis."

The examination for the Radcliffe Travelling Fellowship will begin on March 1. Candidates must have passed all the examinations for B.A. and B.M. in the University, and must either have been placed in one of the First Class in one of the Final Honour Schools, or have taken some University prize open to all.

Cambridge.—Mr. R. H. Biffen, of Caius, has been appointed Demonstrator of Botany; Mr. F. C. Kempson, also of Caius, Demonstrator of Anatomy; and Mr. H. W. Pearson, of Christ's, Assistant Curator of the Herbarium.

The honorary degree of M.A. has been conferred on Dr. H. A. Giles, Professor of Chinese, and on Dr. W. H. R. Rivers, of St. John's, Lecturer in Experimental Psychology.

Two Shuttleworth Scholarships in Botany and Comparative Anatomy will be awarded at Caius College in March. Candidates must be medical students of not less than eight terms' standing. The value of the scholarships is 55*l.* a year for two or three years. Applications are to be made to the tutors by March 1.

M. GERNEZ, *maître de conferences* at the Paris Normal School, has been nominated director of the chemical research laboratory, in succession to the late M. Joly.

PROF. FRANK CLOWES has been elected Emeritus Professor of Chemistry in the University College, Nottingham, on accepting the position of chief chemist and chemical adviser to the London County Council. He will thus retain his professorial title and status, though no longer performing professorial duties. The following is the resolution of the College Committee:—"Resolved that in recognition of the valuable services rendered to the College by Prof. Clowes, first in organising the Chemical Department, and afterwards for sixteen years discharging the duties of Chemical Professor, and for three years the duties of Principal, an honorary position of Emeritus Professor of this College be conferred upon him."

THE Somerset County Education Committee assists technical education in the county in a number of ways, but no branch of its work is likely to prove of more permanent value than the system of aids to public secondary schools, for the purposes of securing efficient teaching of scientific and technical subjects. These grants usually take the form of capitation grants, with the provision that, if made at all, the minimum amount will be 100*l.* per annum. Schools receiving the grants are open at all times, without previous notice, to inspection by Mr. C. H. Bothamley—the Director of Technical Instruction—or other officer appointed for the purpose by the County Committee. It is satisfactory to find that the increased efficiency of the schools which has resulted from the aid and supervision of the County Committee has led in several instances to a marked increase in the number of pupils attending them. In addition to annual grants the Committee has aided schools by grants for building and equipment. There are, however, still considerable areas of the county in which a supply of efficient secondary education is almost entirely wanting. But the report of the County Committee points out that until local authorities receive the wider powers which it is hoped may be given to it by a Secondary Education Act, it will be almost impossible to provide for boys and girls that adequate supply of secondary education of a modern type, which, it cannot be too often repeated, is the only foundation on which it is possible to rear a system of higher technical education such as will bring the higher sections of the industrial community in this country up to the same level of knowledge of their work as their competitors in foreign countries. It is also now becoming generally recognised that secondary education of the kind referred to is rapidly becoming indispensable to every one who desires to occupy a position of control and responsibility in his particular calling in life, whether he afterwards endeavours to add any higher technical training to his general education or not. The Somerset Committee fully recognise this educational principle, and their report shows that they act upon it so far as teey are able.

SCHOOLS of Science carried on in connection with the Department of Science and Art are schools in which systematic courses of instruction are followed. When these conditions are fulfilled, and a fair proportion of students take advanced courses, a special grant is made to the schools in addition to the ordinary grants. Recently, the Inspectors of the Department were given instructions to report on all cases of Schools of Science where the students leaving at the end of the first year, or at the end of the second year, exceeded twenty-five per cent., the idea being that such schools had no claim to be recognised as true Schools of Science, for a sufficient proportion of the students did not continue the systematic course of work laid down. This action of the Department has met with considerable opposition from teachers and school authorities who wish to obtain the special grant without being qualified for it. Numerous schools which do not fulfil, and never expect to fulfil, one of the essential conditions upon which the institution of a special grant to Schools of Science was originally approved, are yet claiming the special grant for such schools instead of the ordinary grant. The Department has now issued a second memorandum stating that it is not desired to press unduly, by any hard and fast rule of percentage, on those schools which may, if time be allowed them, establish themselves as Schools of Science, when it is clear that there is a *bonâ fide* effort to make them such. More than this cannot very well be conceded, for grants can be earned for instruction in any ordinary science or art school or class, without the creation of a School of Science, in the same form as in a School of Science, *i.e.* on attendance. These grants are large, though not on so high a scale as in a School of Science. The Departmental Circular points out that the only justification of a grant higher than the ordinary one is that the school which receives it should fulfil conditions which are not required from ordinary schools and classes. Whether the conditions required should be in any way modified can only be properly considered when the information called for by the Department has been obtained.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, December 1897.—In accordance with the amended by-laws of the Society (May 29, 1897), by which it was arranged that four New York meetings annually should be held instead of eight, as previously, viz. on the last Saturdays of October, February and April, and an annual meeting in the last week of December, a meeting was held on October 30. The object of the change is to secure greater prominence and interest for each meeting, and to afford the members of the Society a better opportunity for scientific and social intercourse. Each meeting now extends through two sessions, held in the morning and afternoon. Forty-one persons (thirty-seven members) were present, and this after the recent successful meeting at Toronto. Nine papers were read, of which abstracts are given here. Some of the papers are printed in the present number, and others will be published in journals whose titles are given.—Note on hyper-elliptic integrals, by Prof. A. S. Chessin, is one of the papers. If X_r is a polynomial in x of degree r; and $P_m(x)$, $Q_n(x)$, . . . polynomials in x of degrees m, n, . . . , we know that the integration of

$$\int f(x, \sqrt{X_r})dx,$$

where

$$f(x, \sqrt{X_r})$$

is a rational function of x and $\sqrt{X_r}$, is reduced to the integration of

$$\int \frac{R(x)dx}{\sqrt{X_r}} \quad (i),$$

where $R(x)$ is a rational function of x. Prof. Chessin gives a practical rule for the integration of (i).—Certain classes of point transformations in the plane, by Dr. E. O. Lovett, was read at the May meeting. It is proposed to apply the transformations to plane curves (spirals) in a subsequent note. The properties discussed and the points of view differ sufficiently (in the author's opinion) from the forms discussed by Laisant (*Nouvelles Annales*, 1868, p. 318) to warrant its publication.—Prof. H. B. Newson in a paper, read at the April meeting, entitled "Continuous groups of circular transformations," has for his object the presentation of the outlines of a fairly complete theory of the continuous groups of linear fractional transformations of one variable. His method differs from the methods of Lie.—Dr. C. A. Scott, in her review of "Julius Plücker's Gesammelte Mathematische Abhandlungen" (edited by A. Schoenflies, 1895), gives a very interesting sketch of this first volume, which contains thirty-nine memoirs by Plücker and Clebsch's "Gedächtnissrede" from the sixteenth volume of the *Göttingen Abhandlungen*. From the "Notes" we learn that Prof. Newcomb, the President of the Society, had chosen the philosophy of hyperspace as the subject of his address at the annual meeting (December 29, 1897).—The valuable list of new publications covers a wide field of mathematical work.

Bulletin de l'Académie des Sciences de St. Pétersbourg, 1896. Tome v. No. 3.—Report of the work of the Russian Archæological Institute at Constantinople, by Th. Ouspensky. The chief work of the Institute is the collection and the study of antiquities; excursions to Trebisonde, Samsun, Sinope and Athens were organised for this purpose. A library and a small museum have been opened.—The declinations of fourteen stars which were observed at Pulkova for the study of the variations of latitude at Kazan, by A. Ivanof.—On vinil-trimethylene and ethylidenetrimethylene, by G. Gustavson.—Short report of a journey to Novaya Zemlya in 1896, for the observation of the eclipse of the sun, by Prince B. Galitzine. The eclipse observations, as is known, were made under fairly favourable conditions, through a light veil of cirrus clouds. After the eclipse, the expedition made an excursion inland in the high mountain region which covers the island in the north-east of Karmakuly. The excursion lasted only nine days. A glacier, two miles long, was discovered at the head of Karmakulka River; very large *neves* are a characteristic feature of this part of the highlands.

No. 4.—Study of the anatomy of *Acanthobdella peledina*, by A. Kowalevsky (in French), with six engravings.—Report of O. Backlund on his journey to Paris and Odessa, for the unification of the constants accepted in astronomical ephemerides.—On the testing of glycerine and the analysis of wax, by F. Beilstein and R. Rinne (in German).—Note on a dry fog observed in Samara.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, January 19.—Annual Meeting.—Mr. R. Trimen, F.R.S., President, in the chair.—The balance-sheet for the past year, showing a balance in the Society's favour and an improvement in the financial position, was read by Mr. A. H. Jones, one of the auditors. The Secretary then read the Report of the Council, from which it was seen that during 1897 the Society had lost 7 Fellows by death and 5 by resignation, and had elected 24, the total number now on the list being 398. The *Transactions* for the year contained 19 memoirs, illustrated by 11 plates, and extending to 434 pages. As a mark of respect to the late Mr. J. W. Dunning, the Council had decided to present his portrait as a frontispiece to the volume of *Transactions* for 1897. It was announced that the following Fellows had been elected as Officers and Council for 1898:—President: Mr. R. Trimen, F.R.S. Treasurer: Mr. R. McLachlan, F.R.S. Secretaries: Mr. W. F. H. Blandford and Mr. F. Merrifield. Librarian: Mr G. C. Champion. Other Members of Council: Mr. W. Bateson, F.R.S., Dr. T. A. Chapman, Sir G. F. Hampson, Bart., Mr. M. Jacoby, Mr. A. H. Jones, Dr. P. B. Mason. Mr. O. Salvin, F.R.S., Mr. J. W. Tutt, Mr. G. H. Verrall, and Mr. C. O. Waterhouse. The President nominated as Vice-Presidents Sir George Hampson, Mr. McLachlan, and Mr. Verrall, and his address was then read on his behalf by the Secretary. After briefly reviewing the position of the Society, and referring to the losses sustained by deaths during the past year, especially those of Dr. Fritz Müller, Mr. J. W. Dunning, and Captain E. Y. Watson, the President proceeded to review the subject of mimicry. (An abstract of his address is printed in another part of this issue of NATURE.) On the motion of Lord Walsingham, seconded by Mr. F. D. Godman, a vote of thanks to the President for his able and exhaustive summary of the subject, and for his services during the past year, was carried by acclamation.

Geological Society, January 5.—Dr. Henry Hicks, F.R.S., President, in the chair.—On the structure of the Davos Valley, by A. Vaughan Jennings. Evidence was brought forward to show that the level area, about four miles in length, near Davos, is occupied by superficial deposits, and that the lateral talus-fans there have been cut through at a relatively recent date since their accumulation; that the northern end towards Wolfgang is blocked by moraine-material of great thickness, but for which the Davoser See would drain north to the Landquart, carrying with it the waters of the Fluela and Dischma; that the contour-lines suggest the former existence of a far larger lake stretching south towards Frauenkirch, and that in that part there is proof of the previous existence of a great detrital fan sufficient to account for the existence of the lake in question.—Sections along the Lancashire, Derbyshire, and East Coast Railway between Lincoln and Chesterfield, by C. Fox-Strangways. The portion of the line considered in this paper occupies a distance of about forty miles, and runs nearly at right angles to the strike of all the beds from the Lias to the Coal Measures.

Royal Meteorological Society, January 19.—Mr. E. Mawley, President, in the chair.—The Secretary read the report of the Council for the year 1897, showing that there had been an increase in the number of Fellows and that the finances were satisfactory.—The President, Mr. Edward Mawley, then gave an address on weather influences on farm and garden crops, in which he pointed out the intimate connection between meteorology, agriculture and horticulture. He explained the special characteristics of the climate of the British Isles as regards temperature, rainfall, &c. Of all the influences brought to bear on vegetable life by the atmosphere, he considered temperature to be the most powerful and far reaching, and only second to this came rainfall. The leading effects of snow, wind and sunshine, as well as of prolonged droughts, severe frosts and persistent rains, were also described. He then dealt with the influence of different important weather changes on such farm crops as wheat, roots, grass, &c., as well as on fruit trees, vegetables, and flowering plants in the garden. In his concluding remarks he called attention to the great want of experimental farms in conjunction with meteorological stations being established in this and other countries in Europe. For it was only by the examination of meteorological observations, together with weekly records of the extent and character of the growth made by our leading crops, that the close connection existing between weather changes and their influences on such crops could be clearly traced.—Mr. F. C. Bayard was elected President for the year.

Zoological Society, January 18.—Dr. Albert Günther, F.R.S., Vice-President, in the chair.—The Secretary exhibited, on behalf of Prof. Robert Collett, a specimen of a supposed hybrid between the Fieldfare (*Turdus pilaris*) and the Redwing (*T. iliacus*).—Mr. W. E. de Winton exhibited and made remarks on a skin of a zebra from British East Africa, belonging to a form described by Herr P. Matschie as *Equus burchelli böhmi*, obtained by Captain S. L. Hinde at Machakos.—Mr. L. W. Byrne read a paper on the general anatomy of the fishes of the order *Holocephali*. The paper contained a brief account of the anatomy of the soft parts of *Chimæra monstrosa* and *Callorhynchus antarcticus*, and a comparison of them with a typical Elasmobranch such as *Scyllium*.—Dr. W. G. Ridewood read a paper on the development of the hyobranchial skeleton of *Alytes*, in which he showed that of the two axial cartilages present in the larval hyobranchial skeleton of this Batrachian, the anterior one disappears completely, while the posterior, which is remarkable in extending back to the laryngeal sinus, persists as the central part of the body of the hyoid.—Mr. F. O. Pickard-Cambridge read a paper on the Cteniform Spiders of Africa, Arabia, and Syria, which contained a list of the species already described from these countries, with notes on their identities, and descriptions of nine new species.—Mr. L. A. Borradaile gave an account of the Crustaceans of the order Stomatopoda represented in the collections made by Messrs. J. S. Gardiner and Dr. A. Willey in several of the South Pacific Islands. Ten species were enumerated, of which three, viz. *Gonodactylus espinosus*, *Pseudosquilla oxyrhyncha*, and *Squilla multituberculata*, were described as new.

EDINBURGH.

Royal Society, January 17.—Rev. Prof. Flint in the chair.—Dr. Hugh Marshall read a note on the axes of symmetry which are crystallographically possible. In this paper the author gave a proof simpler than that of Gadolin ("Mémoire sur la déduction d'un seul principe de tous les systèmes crystallographiques avec leurs subdivisions"), namely, that if the law of rational indices be assumed, only digonal, trigonal, and hexagonal axes are possible with crystals. The proof rests on the assumptions, that an axis of symmetry is necessarily a possible edge or zone axis, and that there are possible edges perpendicular to any axis of symmetry, *i.e.* that the plane to which it is normal is a possible face. These assumptions are formally proved, and then the proposition that an axis of symmetry of the nth order is crystallographically possible only when $\cos 2\pi/n$ is rational, is proved generally. The value of n is limited by the laws of rational indices to those cases where $\cos 2\pi/n$ is rational. Further, from the nature of an axis of symmetry, n must be a whole number. It is shown by N. Boudaief, in the appendix to Gadolin's paper, that the only values of n which satisfy these two conditions are 2, 3, 4, and 6. Consequently only digonal, trigonal, and hexagonal axes of symmetry are possible with crystals.—Prof. Geikie communicated a paper, by Mr. John S. Flett, on the Old Red Sandstone of the Orkneys.—Dr. R. H. Traquair, F.R.S., had a paper on the fossil fishes of the Orcadian series of the Old Red Sandstone of Scotland. As many as fifty-eight species of fossil fishes had been, up to 1888, named and described from the Orcadian rocks of the Moray Firth area, of Caithness, and of Orkney; but Dr. Traquair showed that their nomenclature had fallen into a state of chaos, principally by the unnecessary multiplication of species upon deceptive characters, as well as, to some extent, by the confusion of forms which actually were distinct. The previous list was accordingly reduced from fifty-eight to twenty-four, while, during the past ten years, Dr. Traquair has added nine new species, making the entire number up to thirty-three. Of these new species, three are described for the first time in the present paper, namely, *Homocanthus crassus* and *Asterolepis orcadensis*, from Orkney; *Cheirœanthus striatus*, from Caithness. The rest of the paper consisted of an enumeration of the genera and species of Orcadian fossil fishes, their synonymy, and the localities in which they are found in the three areas—Moray Firth, Caithness, and Orkney. No fishes have been found as yet in the Orcadian beds of Shetland. Of the thirty-three species, twenty-seven occur in Caithness, twenty-four in Orkney, and seventeen in the Moray Firth beds, the small number in the last-named area being apparently due to the absence of certain geological horizons, which are represented both in Orkney and in Caithness. The paper was illustrated by limelight pictures of the principal forms of Orcadian fossil fishes, both as they occur in the rock and as restored by the author.

Mathematical Society, January 14.—Mr. J. B. Clark, President, in the chair.—The trisection of a given angle, by Mr. Lawrence Crawford.—The centre of gravity of a circular arc, by Mr. G. E. Crawford.—A demonstration of the apparatus used in practical skiagraphy by the Röntgen rays was given by Dr. Harry Rainy.

PARIS.

Academy of Sciences, January 17.—M. Wolf in the chair. —Notice of the life and works of M. d'Abbadie, by M. Hatt.—On some results relating to the phenomena discovered by M. Zeeman, by M. A. Cornu. Further improvements in the methods of observation give results not altogether agreeing with those of the original experiments. The action of the magnetic field upon the period of vibration of the radiations from a luminous source appears to depend not only upon the chemical nature of the source, but also on the nature of the group of rays in the spectrum to which each radiation belongs, and on its function in this group. If the direction of the field observed is normal to the lines of force, each ray becomes four, and not three as originally announced by Dr. Zeeman.—Remarks by M. Henri Becquerel on the preceding communication.—On the separation and estimation of iodine, bromine, and chlorine, by M. Ad. Carnot. The separation is based upon the removal of iodine by carbon bisulphide after acting upon the mixture with nitrous vitriol; the bromine is then set free by chromic acid at 100°, and removed by the same solvent. Fairly satisfactory analytical results are appended.—On the decimal hour system, the divisions of the day and the circle, and the geographical table, by M. Henride Sarrauton.—Occultation of the Pleiades by the moon, January 3, 1898, observed at the University of Paris, by M. G. Bigourdan.—Occultation of the Pleiades group, observed at Lyons, by M. Ch. André.—On the four large planets, by M. Émile Anceaux. Certain simple numerical relations have been found to exist between the masses and major axes of orbits of Jupiter, Neptune, Saturn, and Uranus.—On the representation of uniform analytical functions, by M. Paul Painlevé.—On the convergence of series representing the integrals of differential equations, by M. Paul Staeckel.—On the irregular integrals of linear differential equations, by M. J. Horn.—On the existence of integrals of a partial system, determined by certain initial conditions, by M. Riquier.—On the systems of triply orthogonal surfaces where the surfaces of a family admit of the same spherical representation of their lines of curvature, by M. Maurice Fouché.—On the basis of projective geometry, by M. H. G. Zeuther.—On the problem of the cooling of a heterogeneous bar, by M. W. Stekloff.—On gas mixtures, by M. A. Leduc. The author proposes to replace Dalton's law, that the pressure of a mixture of gases is equal to the sum of the pressures that each would occupy in the same receptacle, by another, that the volume occupied by a mixture of gases is equal to the sum of the volumes that the component gases would occupy under the conditions of pressure and temperature of the mixture, the two statements being only identical when Boyle's law holds exactly.—Determination of the density of gases on very small volumes, by M. Th. Schlœsing, jun. The method described gives very fair results with quantities of gas as small as 6 c.c., and requires neither the use of a barometer nor a balance. A column of the gas whose density is to be determined is balanced hydrostatically against a column of gas of known density and absorbable by caustic potash, such as carbon dioxide. The manipulation and calculation are extremely simple. Further details and numerical results will be given in a later paper.—On an apparatus called the hermetical pourer, by M. R. Personne de Sennevoy. With the apparatus in question, a diagram of which is given, a portion of a liquid contained in a hermetically closed vessel can be extracted without introducing any other fluid into the vessel.—On the thermodynamic potential, by M. A. Ponsot.—On the spectrum of the kathode rays, by M. Birkeland.—On the spectrum of cadmium in a vacuum tube, by M. Maurice Hamy. The wave-lengths of the ten principal lines were measured with an accuracy of six significant figures.—On the absolute value of the magnetic elements on January 1, 1898, by M. Th. Moureaux. The calculations are made for the elements at Paris, Nice and Perpignan.—Contribution to the study of the electric furnace, by MM. Gin and Leleux.—New method for measuring the intensity of a magnetic field, by M. E. Bouty. A liquid conductor is allowed to flow normally to the lines of force in the field to be measured. The constant electromotive force induced in the liquid vein is measured by means of the capillary electrometer. It was found that tap water served very well for the conducting liquid, and by increasing the velocity of flow the sensitiveness of the method can be increased almost indefinitely. The fields measured were of the order of 0 5 C.G.S. units.—On a thermometric mercury ammeter, by M. Ch. Camichel. A thermometer bulb is placed in a glass tube slightly larger, and the narrow annular space filled with mercury through which the current is passed. The instrument described measures up to 2 amperes with an approximation of 1/200th.—Discharge by the Röntgen rays. Secondary effect, by M. Jean Perrin. The hypothesis provisionally put forward of a superficial phenomena is now shown to be improbable.—On the electrical resistance of crystallised silicon, by M. Fernand Le Roy. The resistance of silicon is about 1300 times that of electric light carbon, and diminishes on heating, a decrease of about 40 per cent. corresponding to a rise of 800° C.—On some new compounds of the cerite metals, by M. Andre Job.—On aldehyde ammonia, by M. de Forcrand. Calorimetric data of the solutions of this substance.—On β-isopropyl-γ-acetylbutyrate of ethyl and on the stereoisomeric acids derived from it by condensation, by MM. Ph. Barbier and V. Grignard.—On the oxidation of ammonia compounds by the ferments of the soil, by M. E. Demoussy. Under the influence of the bacteria of the soil the amines are oxidised to ammonia, and this goes to nitrite and nitrate in the usual manner. The more complex the amine the slower is the course of oxidation.—Bacilli of beriberi, by M. Gustave Nepveu. Three forms of bacilli differing in size (8 μ, 3 μ for the two larger) were found, but it is not quite certain that these are distinct forms.—On the structure of the cirrophore in the Polynoïdia, by M. G. Darboux, jun.—On the elongations of the anterior portion of the body of the Prosobranchia and their influence upon the corresponding region of the digestive tube, by M. Alex. Amaudrut.—On a cœlomic gregarian presenting a phase of asporulic multiplication in the evolutive cycle, by MM. Maurice Caullery and Félix Mesnil. The new species is a parasite in the general cavity of *Dodecaceria concharum*, and is named *Gonospora longissima*. —Sex and molecular dissymmetry, by M. Félix Le Dantec.—Some remarks by M. Edmond Perrier on the preceding paper.—On the supposed chloragogenesis of the general cavity of the Opheliæ, by MM. J. Kunstler and A. Gruvel.—On the existence of a malacological polybathic fauna at great depths in the Atlantic and Mediterranean, by M. Arnould Locard. Outside the well-defined littoral zones there exists both in the Atlantic and Mediterranean a fauna capable of living and developing at depths of over 2000 metres, to which the name polybathic is given. This fauna contains many Gastropods, and is especially rich in Scaphopods and Lamellibranchs.—On the origin of the double sheath of the root of *Tropælum*, by M. Camille Brunotte.—On the preparation of gentianose, by MM. Ed. Bourquelot and L. Wardin.—On the germination and hibernal fructification of the truffle, by M. A. de Gramont de Lesparre.—On the mineral layers of oolitic iron of the new basin of Briey, by M. Georges Rolland. Complete geological sections of these important beds of Meurthe-et-Moselle are given.—On the caverns of Sauve (Gard), and the form of the reservoirs of springs and calcareous soils, by MM. E. A. Martel and A. Viré.—Considerations on the oceanic circulation in the Bay of Biscay, by M. I. Thoulet.—Observation of a double meteor, at Vannes, on January 3, 1898, by M. Georget.—Remarks by M. Callandreau on the preceding note.

In the abstract of the *Comptes rendus* of the meeting of the Paris Academy of October 26, a paper by M. Gaston Séguy on a new method of reducing the time of exposure in radiography was referred to (November 4, 1897, p. 24). Dr. Max Levy writes from Berlin to call attention to the fact that the method described originated with him, and that M. Séguy acknowledged such to be the case in the course of the paper communicated to the Paris Academy.

NEW SOUTH WALES.

Linnean Society, November 24, 1897.—Prof. J. T. Wilson, President, in the chair.—The President formally announced the death of Prof. T. Jeffery Parker, F.R.S., of Dunedin, a corresponding member of the Society, on November 7. It was resolved that an expression of sympathy from the Society should be tendered to Prof. Parker's family.—The President commended to the favourable notice of the members the report of a meeting held at Melbourne, for the purpose of forwarding the movement to establish some permanent memorial of the late Baron von Mueller. It was resolved that it was desirable that steps should be taken to commemorate in some suitable way the late Baron's work, and an influential committee was appointed to carry out the proposal. It is hoped that a sufficient sum of money will be forthcoming to provide for a bust or medallion of the Baron, as well as for the endowment of a medal or prize to be associated with the Baron's name, and to be awarded from time to time in recognition of botanical, pharmaceutical, or horticultural work in the various Australasian Colonies. Subscriptions in aid of this project may be sent to Prof. Baldwin Spencer (The University, Melbourne), one of the hon. secretaries.—Plants of New South Wales, illustrated. Part ix., by R. T. Baker. The species figured and treated of are *Acacia gladiiformis*, A. Cunn., *A. obtusata*, Sieb., *A. rubida*, A. Cunn., and *A. triptera*, Benth., var. nov.—On some New South Wales Fungi, by D. McAlpine. Seven species occurring on the leaves or bark of indigenous trees are recorded. Of these four are described as new, and two are recorded from this Colony for the first time.—Observations on the Eucalypts of New South Wales. Part iii., by Henry Deane and J. H. Maiden. In this third contribution the species dealt with are *Eucalyptus haemastoma*, *E. Sieberiana*, *E. stricta*, *E. obtusiflora*, and some allied forms.—On some Australian *Eleotrinæ*. Part ii., by J. Douglas Ogilby. Five additional species of Australian eleotrins are described.—On two new Australian fishes, by J. Douglas Ogilby. The two species described are *Harengula stereolepis*, from Torres' Straits, and *Decapterus leptosomus*, a mackerel-scad which annually visits Port Jackson but has hitherto escaped notice.—A contribution to the zoology of New Caledonia, by J. Douglas Ogilby. After alluding to the meagreness of our knowledge of the biology of the island, the author gives a list of the fresh-water fishes referable to six species brought back by Mr. Hedley, with observations thereon.—On Australian *Termitidæ*. Part iii., by W. W. Froggatt.—Eleven species of *Termes*, of which ten are new, and seven species of *Eutermes*, of which five are new, are described. In most cases some account of the nests is also given.—On new Marine Mollusca from the Solomon Islands and Australia, by John Brazier. The Volute described at last meeting from an imperfect specimen is redescribed from a perfect example which subsequently became available. Descriptions also are given of a new cone from Flinders, Victoria, of two from the Solomon Islands, and of a species of *Axinæa* from the Gippsland Lakes Entrance, Victoria.—Observations on Papuan land and fresh-water shells, with descriptions of new species from New Guinea and Western Australia, by C. F. Ancey. From Western Australia the new species *Trachia Froggatti*, *T. orthocheila* and *T. monogramma* are described and figured from material collected by Mr. W. W. Froggatt. New Papuan shells from German New Guinea are *Sulcobasis leptocochlea* and *Chloritis Möllendorffi*, with which is figured *Pupina Beddomei*, described in an earlier volume of the Society's *Proceedings*. Critical observations on sundry Australian and Papuan shells conclude the paper.—Mr. R. T. Baker exhibited specimens of camphor and camphor oil obtained from the leaves of *Cinnamomum Oliveri*, Bail. The yield of camphor is about ½ per cent. It resembles in odour and appearance the ordinary camphor of commerce. Its melting point was between 173·5 and 175, the melting point of ordinary camphor being given as 175° C. Its specific rotation is also almost identical with that of common camphor. The camphor oil was obtained with the camphor, both floating on the surface of the water, and was separated by pressure. The amount of oil was equal to ·364 per cent., but still retained some camphor in solution.—Mr. R. Etheridge, jun., exhibited some drawings of undetermined leaves, presumably of Tertiary age, from Rollo's Shaft, Coolgardie, forwarded by the Government Geologist of West Australia to Mr. H. Deane. Also specimens of leaves, at present undetermined, from a quarry on the Diamantina River, near Birdsville, a little over the Queensland and S. Australian border, in the former Colony, lat. 25° 55′ S., and long. 138° 25′ E. approximately. Mr. R. L. Jack states that Birdsville is "a Lower Cretaceous locality, but it is quite possible that there are desert sandstone tablelands in the neighbourhood, and the plants may come from one of these."—Mr. Edgar R. Waite exhibited (1) examples of *Typhlops aluensis*, Blgr., from Wai Obi, Vuna Pi, Fiji, where they are known to the natives as "Naota." This species was previously known only from the Solomon Islands, and the new record supplies further evidence of the similarity of the faunas of the two Archipelagoes. (2) A New Zealand fish (*Neptotichthys violaceus*, Hutton) recently caught in Port Jackson, and the first recorded occurrence in Australian waters. (3) Two photographs taken at Layson Island (Hawaiian Islands); one exhibits an immense concourse of albatrosses (identified by Mr. A. J. North as *Diomedea immutabilis*, Rothschild) incubating their eggs, and the other the method of collecting and transporting the eggs. This photograph shows, in addition to wheelbarrows and boxes, two railway trains, the wagons of which are literally piled up with eggs. (4) A block of limestone from the Jenolan Caves polished by Rock Wallabies (*Petrogale penicillata*, Gray).—Mr. Fred. Turner sent for exhibition a series of specimens of the grass *Danthonia pilosa*, R.Br., from near Finley, Riverina, with the inflorescence affected with a parasitic fungus. Fifteen other species of Australian grasses were known to him as subject to similar attacks. The subject of the effects produced upon stock by feeding on diseased grasses was one well worth investigation.—Mr. Palmer showed a specimen illustrating what he thought might be considered an undoubted case of root-grafting. Also a clump of the galls of *Brachyscelis duplex*, Schrader, from the Blue Mountains; and a quartz crystal or sacred stone presented to his father by an aboriginal of the Port Stephens tribe, fifty years ago.—Mr. North exhibited the sexes of the rare White-vented Wood Swallow, *Artamus albiventris*, which he had shot on Tyreel Station on the Gwydir River; also the nest and eggs of these birds found at the same time in the top of a hollow stump by Mr. E. Stirton, of Moree. Also some siliceous stones, land-shells, berries, pieces of coloured glass, and a galvanised iron screw procured from a play-house of the Spotted Bower-bird (*Chlamydodera maculata*, Gould) on Weebollabolla Station; the parallel walls of the bower were wholly constructed of dried "spear or corkscrew-grass (*Stipa setacea*) set upright in a slight foundation of fine twigs. Likewise, two sets of the eggs of the Pied Honey-eater (*Certhionyx leucomelas*, Cuvier), procured in Western New South Wales near the South Australian border; and the eggs of another Honey-eater, presumably an undescribed species.

AMSTERDAM.

Royal Academy of Sciences, December 24, 1897.—Prof. van de Sande Bakhuyzen in the chair.—Prof. van Wijhe, on an automatic injector for Teichmann's substance, and presented a paper on it for publication in the *Proceedings*.—Prof. van de Sande Bakhuyzen presented, for publication in the *Proceedings*, (*a*) a paper by J. Stein, of Katwijk, on elements of the planet 424=1896 DF, and ephemeride for 1898; (*b*) on behalf of C. Easton, a paper on the grouping of the stars in the Milky Way; and (*c*) made some remarks on the distribution of stars in space, which will be inserted in the *Proceedings*.—Prof. Schoute continued a communication, presented on his behalf by Prof. Darboux to the Academy of Sciences of Paris, extending his theory, given there, of the determination of focal curves of plane curves in possession of an axis of symmetry to that of the focal surfaces of surfaces, that admit of a plane of symmetry.—Prof. van der Waals presented, on behalf of Dr. P. Zeeman, measurements concerning radiation phenomena in the magnetic field. Photographs have been taken of the outer components of the magnetic triplet. Measurements of the distance of the components for lines in the violet and ultra-violet parts of the spectrum are communicated. In the cases of the metals examined—viz. zinc, cadmium, copper, and tin—the magnetic change is of the same order of magnitude in all of them, and independent of the atomic triplet. Some lines are not affected by magnetism.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 27.

ROYAL SOCIETY, at 4.30.—Mathematical Contributions to the Theory of Evolution. On the Law of Ancestral Heredity: Prof. Karl Pearson, F.R.S —On the Zoological Evidence for the former Connection of Lake Tanganyika with the Sea: J. E. S. Moore.—(1) The Kelvin Quadrant Electrometer as a Wattmeter and Voltmeter; (2) The Magnetic Properties of almost Pure Iron: E. Wilson.

ROYAL INSTITUTION, at 3.—The Halogen Group of Elements: Prof. J. Dewar, F.R.S

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Notes on the Electro-Chemical Treatment of Ores containing the Precious Metals: Major-General Webber, C.B.

FRIDAY, JANUARY 28.

ROYAL INSTITUTION, at 9.—Instinct and Intelligence in Animals: Prof. C. Lloyd-Morgan.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Condensing Apparatus: H. Williams.

MONDAY, JANUARY 31.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Through Somaliland to Lake Rudolf: H. S. H. Cavendish.

INSTITUTE OF ACTUARIES, at 5.30.—Some Remarks on the Valuation of Endowment Assurances in Groups: George J. Lidstone.

TUESDAY, FEBRUARY 1.

ROYAL INSTITUTION, at 3.—The Simplest Living Things: Prof. E. Ray Lankester, F.R.S.

ZOOLOGICAL SOCIETY, at 8.30.—On a Collection of Fishes from the Rio Jurua Brazil: G. A. Boulenger, F.R.S.—On the Anatomy of an Australian Cuckoo (*Scythrops novæ-hollandiæ*): F. E. Beddard, F.R.S.—On a Collection of Lepidoptera made by Mr. F. V. Kirby, chiefly in Portuguese East Africa: Dr. A G. Butler.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Paper to be further discussed: Reservoirs with High Earthen Dams in Western India: W. L. Strange.

MINERALOGICAL SOCIETY, at 8.—Canfieldite from Bolivia; Specific Identity of so-called "Crystallised Brongniartite" and Canfieldite: G. T. Prior and L. J. Spencer.—On Atacamite from Sierra Gorda, Atacama: G. F. Herbert Smith.

ROYAL VICTORIA HALL, at 8.30.—Insects in a London Back Garden: F. Enoch.

WEDNESDAY, FEBRUARY 2.

SOCIETY OF ARTS, at 8.—The Cinematograph: Jules Fuerst.

GEOLOGICAL SOCIETY, at 8.—Contributions to the Glacial Geology of Spitsbergen: Dr. J. W. Gregory and E. J. Garwood.—On a Quartz-rock in the Carboniferous Limestone of Derbyshire: H. H. Arnold-Bemrose.

ENTOMOLOGICAL SOCIETY, at 8.—On the Larva of Pelophila: Rev. W. F. Johnson and G. H. Carpenter.—New Species of American Rhopalocera. F. D. Godman, F.R.S., and O. Salvin, F.R.S.

THURSDAY FEBRUARY 3.

ROYAL SOCIETY, at 4.30.—*Probable Papers:* Comparison of Oxygen with the Extra Lines in the Spectra of the Helium Stars β-Crucis, &c.; also Summary of the Spectra of Southern Stars to the 3½ Magnitude and their Distribution: F. McClean, F.R.S.—The Intimate Structure of Crystals. Part I. Crystals of the Cubic System with Cubic Cleavage—Haloid Salts of the Alkalies: Prof. Sollas, F.R.S.—Researches in Vortex Motion. Part III. On Spiral or Gyrostatic Vortex Aggregates: Prof. W. M. Hicks, F.R.S.—The Pharmacology of Aconitine, &c., considered in relation to their Chemical Constitution: Prof. Cash, F.R.S., and Prof. Dunstan, F.R.S.

ROYAL INSTITUTION, at 3.—The Halogen Group of Elements: Prof. J. Dewar, F.R.S.

LINNEAN SOCIETY, at 8.—On the Muscular Attachment of the Animal to its Shell in some Fossil Cephalopoda (Ammonoidea): G. C. Crick.—The Comparative Anatomy of certain Genera of Cycadaceæ: W. C. Worsdell.

CHEMICAL SOCIETY at 8.—Effect of the Mono-, Di-, and Tri-chloracetyl Groups on the Rotatory Power of Methylic, and Ethylic Glycerates and Tartrates: Percy Frankland, F.R.S., and Dr. Thomas Stewart Patterson.—The Rotation of Ethylic and Methylic Di-monochloracetyltartrates: Percy Frankland, F.R.S., and Dr. Andrew Turnbull.—The Volumetric Estimation of Sodium: H. J. H. Fenton.

FRIDAY, FEBRUARY 4.

ROYAL INSTITUTION, at 9.—Some New Studies in Kathode and Röntgen Radiations: A. A. Campbell Swinton.

GEOLOGISTS' ASSOCIATION, at 7.30.—Annual General Meeting.—Palæolithic Man: E. T. Newton, F.R.S., President.

SATURDAY, FEBRUARY 5.

ROYAL INSTITUTION, at 3.—Cyprus: Prof. P. Geddes.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Nature Study in Elementary Schools: Mrs. Wilson (Macmillan).—Complete Perspective Course: J. H. Spanton (Macmillan).—Practical Electricity and Magnetism: J. Henderson (Longmans).—Ignorance: M. R P. Dorman (K. Paul).—United States Geological Survey: Atlas to accompany Monograph xxviii. on the Marquette Iron-bearing District of Michigan: Van Hise, Bayley, and Smyth (Washington).—Sewer Gas and its Influence upon Health: H. A. Roechling (Biggs).—Traité de Zoologie Concrète: Y. Delage and E. Herouard. Tome v. Les Vermidiens (Paris, Reinwald).—Le Rationnel; G. Milhaud (Paris, Alcan).—Floods of the Mississippi River: P. Morrill (Washington).—Calendario del Santuario di Pompei, 1898 (Valle di Pompei).—Marcello Malpighi e l'Opera Sua (Milano, Dr. F. Villardi).

PAMPHLETS.—Étude sur la Théorie des Comètes Périodiques: M. O. Callandreau.—A Mechanical Cause of Homogeneity of Structure and Symmetry geometrically investigated: W. Barlow (Royal Dublin Society).—A Paper on the Foundations of Projective Geometry: E. T. Dixon (Cambridge, Deighton)—Harmonic Curves of Three Frequencies: Prof. C. S. Slichter (Wisconsin).

SERIALS.—The Garden, Orchard and Woodland, January (Southampton Street).—Engineering Magazine, January (222 Strand).—Journal of the Royal Statistical Society, December (Stanford).—Proceedings of the Physical Society of London, December (Taylor).—Psychological Review, January (Macmillan).—Essex Institute Historical Collections, Vol. xxxiii. APPLIED MECHANICS, AND THE WAY TO TEACH IT.

Applied Mechanics: a Treatise for the Use of Students who have time to work Experimental, Numerical, and Graphic Exercises illustrating the Subject. By John Perry, D.Sc., F.R.S. Pp. v + 678. (London: Cassell and Co., Ltd., 1897.)

PROFESSOR PERRY'S position in the Department of Science and Art gives him so wide an influence on the teaching of applied mechanics throughout the country, that a book which expounds and exemplifies the method of teaching he approves will be received with keen interest. But the volume before us has no need of any adventitious claim on the attention of readers. Prof. Perry has the knack of throwing his personality into his books. You may not always agree with him: indeed, nothing would distress him more than to find you doing that; for what is the use of trailing a coat unless a gentleman will be so good as to tread on it? But, at any rate, you will not find him dull. He holds you alike by what he says and how he says it. You recognise in every chapter the fulness of his knowledge, the ripeness of his experience, the freshness of his methods, the individuality of his style. It is a style which some of us are too steeped in convention to enjoy without qualification. I must myself confess to a measure of distaste for the "Clarendons" which flash out every here and there over the printed page, not in headlines, but to emphasise words and phrases in the text. And the numerous "asides" about educational methods and other things are oddly placed in a treatise on applied mechanics. But the most critical reader will find his admiration compelled by the immense amount the book contains of excellent matter not found, or not readily found, elsewhere; and he will admit that the work is pre-eminently alive in every page, and that the author is speaking throughout with a real knowledge of real things.

Prof. Perry describes it as a treatise for the use of students. I should rather say for the use of teachers, and add that every teacher of mechanics should possess himself of a copy. It is certainly not for beginners. A fairly advanced student will find it very helpful, perhaps as a mine in which to dig rather than as a course to be systematically followed. To the teacher of applied mechanics it will prove invaluable, and through him its influence will, I believe, be far-reaching.

It is clear enough that Prof. Perry is addressing the teachers at least as much as the taught. Else what mean the frequent homilies on teaching, such as these?

"We believe that the principles which an engineer really recollects and keeps ready for mental use are very few. . . . We ought to teach him how to learn for himself. Any child can state Newton's second law of motion, and the other half-dozen all-important principles of mechanics, so as to get full marks in an examination paper; the engineer knows that the phenomena he deals with are exceedingly complex, and that only a long experience will enable him to utilise the so easily stated principles" (p. [illegible]).

"The most important lesson for a beginner, however he may have studied mathematics and mechanics, and however able he may be as a mathematician, is this—that he must not go on merely assuming that he knows how to do things; he must know things by **actual trial**. . . . Teachers will notice that things requiring even a little preparation more than other things will gradually become neglected. . . . When we find our system to be going with clockwork regularity, and we feel no worry, we ought to believe that some change is necessary. If we find that the students are not absorbed in their work, we must understand that we teachers are in fault" (p. 3).

"If it is possible we try to learn all our mathematics, mechanics, physics, and chemistry from teachers who are engineers. What acquaintance with these subjects we have ought to be a real knowledge, and not the glib pretence which suffices for examinations. . . . To effect this object we must work many numerical and graphical exercises, and try to conquer our contempt for simple laboratory experiments" (p. 3).

"Our aim is to get students to think, and it is astonishing how difficult it is to effect this object. . . . In the mechanical laboratory I find that even the dullest student begins to think for himself if he is not too much spoon-fed; and if his difficulties are not cleared away by some wretched routine system of laboratory work being adopted by cheap laboratory instructors, the fundamental principles of mechanics will become part of his mental machinery" (p. 56).

In another passage the author insists, with great truth and force, on the desirability of introducing even elementary students to the fundamental notions and symbols of the calculus at the beginning of their study of applied mechanics. And in another he remarks that "Newton's method, the 'Thomson and Tait method,' is very much to be preferred to any other method of starting in the study of mechanics"; and adds, "Every engineer ought to have his T and T′ (the elementary treatise) a well-thumbed book."

Chapter xi. opens with these rather oracular sentences:

"We sometimes assume that our readers know quite well the fundamental principles of mechanics, and then again we assume that they do not. We hope that they agree with us that we are right in proceeding in this way" (p. 242).

One more passage showing the missionary spirit of the author may be quoted:

"A student who works such an exercise as this carefully is getting all sorts of **valuable notions**, not merely of mechanics but of practical mathematics. Unfortunately, twenty academic exercises can be worked out without much thought or trouble to teacher or student, and by the rules of the game this is sufficient for the passing of examinations. For the present, therefore, my advice will be followed by a few earnest students only—the men who want to know, the men who are not merely in search of examination tips, the men who find academic exercises difficult because they think about what they do" (p. 266).

Like all the rest of the book, these *obiter dicta* are full of interest and suggestiveness. With most of what they contend for the present writer heartily agrees. He is disposed, however, to believe that it is not always through excess of thought that men fail even in "academic" examinations.

One great lesson to be learnt from Prof. Perry is the value of the mechanical laboratory as part of the machinery of teaching. Not merely does he preach this in the passages quoted and in others, but the book is enriched by many examples of the experimental method, and by many illustrations of laboratory apparatus. Readers of Prof. Perry's "Practical Mechanics," of which this book may be regarded as an extension, do not need to be told that in the development of the mechanical laboratory he has done pioneer work of the most important kind. In his preface he refers very properly to the initiative taken by Sir Robert Ball in the teaching of mechanics by quantitative experiments, and he also speaks in altogether too generous terms of work in this direction recently done in the Engineering Laboratory at Cambridge. But it is to Prof. Perry himself that we owe in great measure the idea of a laboratory in which the students themselves carry out such experiments in applied mechanics, and the idea is one for which students, if not teachers, cannot be sufficiently grateful. Nothing contributes so much toward giving men a real and useful grasp of a mechanical principle than they should themselves make quantitative experiments with a piece of apparatus designed to exemplify the principle. But there must of course be some preliminary training in theory, and the work of the laboratory must be in close touch with that of the lecture-room.

In the history of Nicholas Nickleby we are told how Mr. Squeers claimed to "go upon the practical mode of teaching, the regular education system." He taught his boys to spell "winder" and then go and clean it, to spell "bottiney" and then weed the garden. This early and crude example of the laboratory method had two grave defects. The book-work was badly done; and there was no sufficient connection between it and the practical work, for it must be admitted that weeding does not help to spell, nor spelling to clean windows. Add to this that Mr. Squeers quarrelled with his demonstrator, which was impolitic, and that his boys were, in Prof. Perry's words, "too much spoon-fed," and it is not strange that the laboratory method did not commend itself in his hands.

We have changed all that, and as things are now there is perhaps a little danger of the practical work receiving even more than its due share of attention. Valuable as it undoubtedly is, the value of lectures and reading and "paper" work generally is not to be underrated. Prof. Perry does well to insist that the student shall "work many numerical and graphical exercises," as well as "make a great many quantitative laboratory experiments."

By the publication of his "Applied Mechanics" Prof. Perry has made a large addition to the debt which teachers and students of the subject already owe him.

J. A. EWING.

CHARLES CARDALE BABINGTON.

Memorials, Journal, and Botanical Correspondence of Charles Cardale Babington. Pp. xciv + 475. (Cambridge: Macmillan and Bowes, 1897.)

CHAPTERS in the history of the teaching of botany have now been written in the biographies of four Cambridge professors. In 1830 was published Gorham's "Memoirs of John and of Thomas Martyn," a book of small size; and in 1862 Jenyn's "Memoir of the Rev. J. S. Henslow," containing 278 pages. The last of this series, the volume under review, far exceeds the others in size, and contains 570 pages.

The plan of the book divides it sharply into three sections. The first of these sections is occupied by notices from various sources, mostly reprinted from other publications, and diverse in the points from which the views of the different writers are taken. We find Prof. Babington in the light of a college friend from the pen of Prof. J. E. B. Mayor, as a fellow-teacher of science from that of Prof. G. D. Liveing, as a fellow-botanist by Mr. James Britten, as an archæologist, and as a philanthropist. The second section (270 pages) consists of the journal kept by him throughout his long life, and the third section of letters written by him to various botanists. The book closes with a list of his publications, and a very complete index in two parts.

Undoubtedly the greatest interest in the volume lies in the scattered sentences, which refer to the struggle for the recognition of science as an educational subject, in which struggle Babington played no small part. From 1826 until his death in 1895 he resided in Cambridge; and one may remind the reader what an immense change has taken place since the first date, when the Elizabethan statutes were still in force. The early teaching of botany in Cambridge was intermittent. Richard Bradley, professor from 1724 to 1733, seems never to have lectured; John Martyn, his successor, lectured from 1727 to 1734, and Thomas Martyn, who became professor in 1762, lectured for thirty years. In 1825 J. S. Henslow's teaching commenced, and we are told that for seven years his class numbered sixty to eighty. The clearness and charm of Henslow's lectures attracted many of the older members of the University to listen to him, and among these sat for six nearly consecutive years young Babington. After this we learn that the numbers attending the class fell. In 1861 there were no lectures. Babington, meanwhile being elected professor, begins to lecture in 1862, and in 1864 (p. 359) has a class of thirty-five to forty-five students, in 1865 (p. 362) of forty, in 1866 (p. 205) of about forty-five. Such references as these, scattered sometimes in letters, sometimes in his journal, will serve as grist to the mill of a historian wishing to write an account of science in England. The story of Babington's influence for the promotion of natural history, especially in the years before he became professor, is admirably told in Prof. Liveing's memoir on p. lvii.

A regular attendant at the meetings of the British Association, he was one of the founders of the Red Lion Club, a club formed by a little knot of kindred spirits who dined together during the meeting. On p. 85, the founding is thus noticed: "1839. Aug. 29. Yesterday and to-day we formed a private dinner-party at the 'Red Lion' inn (Birmingham), with Dr. Macartney in the chair." Frequent mention of the "Red Lions" occurs in the following pages.

In his letters to J. H. Balfour, A. G. More, and others upon scientific publications, we find him (p. 302) ill-satisfied with the *Phytologist*, and (pp. 288, 291, 306, 312, &c.) very solicitous for the good of Henfrey's *Botanical Gazette* and the *Transactions* of the Edinburgh Botanical Society.

So much for the purely historic side of the book. There occur in the first pages of the journal notes upon insects, and here and there throughout archæological jottings; but the greater part, as one would expect, concerns British plants. The letters are all botanical, and usually express his opinion upon some difficult plant; the journal contains accounts of his "finds" on the excursions which he made in all parts of the British Isles, in the Channel Isles, and in Iceland. Much, indeed, is matter of greater interest to the compiler of a local flora than to the general reader. Yet the history of the changes of opinion upon critical plants, and the notices of the discoveries of forms new to our islands, will appeal to many British field-botanists. To sift the synonymy it is necessary to turn to the first index, where, with the exception of the brambles, the nomenclature of the last edition of Babington's "Manual of British Plants" is followed. One could wish that this sifting of the names had been done in footnotes, in which way it would catch the reader's eye more readily. The index tells us that, on p. 169, *Potamogeton flabellatus* stands for *P. decipiens*, and that *Euphorbia pilosa* appears under five names. Such instances may be here quoted with the remark that reference to this index is very necessary in using the book.

Lastly, in spite of its many pages, the volume is light; the printing is excellent, and the portrait at the commencement a very true likeness. A second portrait, taken at the age of seventeen, occurs at the commencement of the second part, and a pedigree-table occupies a pocket at the end of the book. I. H. B.

DIAMONDS.

Papers and Notes on the Genesis and Matrix of the Diamond. By the late Prof. Henry Carvill Lewis, M.A., F.R.S. Edited from his unpublished MSS. by Prof. T. G. Bonney, D.Sc., LL.D., F.R.S. Pp. 69, with 2 plates and 35 woodcuts. (London: Longmans, Green, and Co., 1897.)

Diamonds. A Lecture delivered at the Royal Institution, Friday, June 11, 1897. By William Crookes, Esq., F.R.S., M.R.I. Pp. 25, with 39 photographs. (*Journal* of the Royal Institution of Great Britain, 1897.)

AMONG the subjects which attracted the attention of the able and versatile geologist of Philadelphia—whose early death was so deeply mourned both in this country and the United States—was that of the mode of occurrence and the origin of the diamond. At the meeting of the British Association at Birmingham in 1886, Prof. Carvill Lewis read a short paper "On a Diamond-bearing Peridotite and on the History of the Diamond"; and in the following year he communicated to the Association meeting at Manchester a much longer and more elaborate paper on the same subject, which was entitled "The Matrix of the Diamond." It was well known to Carvill Lewis's numerous scientific friends in this country that he had collected much valuable evidence concerning the association of diamonds with peridotite and serpentine in all parts of the world, and had arrived at certain very definite views concerning the constant association of the crystalline form of carbon with the ultrabasic rocks.

Geologists are indebted to Prof. Carvill Lewis's widow for the publication of the work, the title of which stands first at the head of this article, in which these two valuable papers have been printed in full, and to Profs. Bonney and Rosenbusch for the painstaking care and sound judgment with which they have been edited. In the opinion of neither the editor himself nor of Prof. Rosenbusch, were the fragmentary notes on the wider and more theoretical questions connected with the origin of the diamond in such a state as would warrant their publication; but Prof. Bonney has been able to add a memoir describing the occurrence of rocks similar to that found in the diamond mines of South Africa—to which Carvill Lewis gave the name of "Kimberlite"—from two localities in the United States. These descriptions are based on information supplied by Mr. J. S. Diller, of the United States Geological Survey, and by the late Prof. G. Huntingdon Williams, of Baltimore, in addition to the notes and specimens collected by the late Prof. Carvill Lewis himself. Geologists now possess, in the work before us, the most complete and satisfactory account of the curious rock in which the diamonds of South Africa are embedded; equal care being devoted to the microscopic structure of the rock, and to the identification of the various minerals present in it.

Turning our attention from the papers of Carvill Lewis to the lecture of Sir William Crookes, it is impossible to avoid being struck with the great advances which have been made, during the last ten years, in our knowledge of the properties and mode of occurrence of that most wonderful and interesting of all minerals—the diamond.

The first part of the lecture of Sir William Crookes is occupied with a popular account of the diamond mines of South Africa and the manner in which they are worked. The author having recently returned from the district, where special facilities had been afforded him for scientific observation, is able to supply a very lively description of the country and its inhabitants, as well as of the operations by which the diamonds are obtained. The reproduction of the photographs with which the lecture was illustrated adds greatly to the value of the pamphlet.

Concerning the properties of the gem, Sir William Crookes is able to supply much valuable information, recently obtained, concerning the intimate relations between diamond and graphite, and the conversion of one material into the other, and also on the action of the Röntgen rays upon the diamond. As a means of distinguishing true diamonds from all kinds of paste imitations, the Röntgen rays appear to be invaluable, for we have here a test which can be applied to cut and mounted materials without any risk of injury to them.

In the decade which has elapsed between the reading of the two scientific communications which we have placed at the head of this notice, the discoveries concerning the mode of occurrence and the artificial formation of the diamond have been of especial importance—and they are admirably summarised by Sir William Crookes in his lecture.

In 1884 Erofeyev and Lachinov showed that an iron meteorite contained diamonds, and this fact was more recently confirmed by Foote's discovery of diamonds in the Cañon Diablo meteorite, and by that of Weinschenk in the meteorite of Ava. Cliftonite, a form of carbon in cubical crystals, detected by Mr. Fletcher in the meteorite of Youndegin in West Australia, may not improbably be regarded as a pseudomorph in graphite after the diamond.

Finally, Moissan's preparation of diamonds by crystallisation from molten iron has at last solved the long-standing problem of the artificial formation of the mineral.

Sir William Crookes suggests both a deep-seated terrestrial, and a meteoric origin as possible for the diamonds found upon our globe—in both cases the agency of iron as the crystallising medium being invoked. It must not be forgotten, however, that the same mineral species has often originated in many different ways, and it is by no means certain that nature in her laboratories—provided as they are with such abundant resources—has been compelled to resort to precisely the same expedients as we have been led to employ in our experimental researches. J. W. J.

OUR BOOK SHELF.

The Constitution and Functions of Gases. Part iii. By Severinus J. Corrigan. Pp. 179. (St. Paul: Pioneer Press Company, 1897.)

THIS volume is a continuation of the "Constitution and Functions of Gases"—the first two parts of which were reviewed in these columns last year—and deals with the applications of the author's theory to questions of astronomy, treating especially with the genesis and development of the solar system, the age of the sun and the earth and the other planets, and the consideration of the earth from its geological aspect.

It may be remembered that the author in the first part of his treatise expounded a new theory of gases, where, instead of the irregular movements of colliding molecules as developed in the theory of Clausius and Maxwell, the molecule is supposed to remain stationary as a whole, but is made up of a large number of electric or magnetic doublets which revolve in approximately circular orbits with enormous velocities. In this way many of the properties of gases can be readily explained, and the solutions of many interesting problems attempted which, in some cases, agree fairly accurately with experimental results. The theory was ingeniously developed to do away with the necessity of an ether for the transmission of light vibrations through space, by substituting for it a gas of extreme tenuity.

By utilising the general ideas of the nebular hypothesis of Laplace, and by applying the equations obtained in the first treatise, the author proceeds to investigate the genesis and development of the solar system, to determine the ages and temperatures of the planets, as well as a multitude of other important facts, which, if they could only be demonstrated, would place the author on a pedestal by the side of Newton as the greatest astronomer of the age. The fertility of resource of the author in developing his ideas is astonishing, and though at all times the theories are intended to be primarily based on known experimental data, this basis is in many cases so slight and uncertain, and the assumptions so numerous, that the results must be looked upon as mere speculations. The author is equally at home discussing the cause of the Noachian deluge, the nature of vegetation on the planet Mars, and the cause and origin of X-rays.

In the treatment of the earth, the duration of every geological epoch and its cause is determined. The great glacial period is discussed, and, according to the author's views, must be ascribed to the varying intensity of the sun's radiation in past ages.

It is impossible in this short space to enumerate a tithe of the wonderful results that the author obtains; but though there is much that is purely visionary, occasionally some very interesting suggestions are advanced which bear the stamp of probability. The book is written from a scientific rather than a popular point of view, and is chiefly of interest as an example of how an ingenious mind can build up a large and comprehensive theory on very slight foundations. E. R.

A Run round the Empire; being the Log of Two Young People who Circumnavigated the Globe. Written out by their father, Alex. Hill, M.A., M.D., Master of Downing College, and Vice-Chancellor of the University of Cambridge. With 42 illustrations. Pp. viii + 286. (London: Swan Sonnenschein and Co., Ltd., 1897.)

THE Master of Downing jokingly lays claim in his preface to the invention of a new system of education—by taking children for a voyage round the world "before the faculty of observation has been stifled by the study of dead languages, mathematics and other abstract subjects, which have no counterpart in our physical environment." The stifling of the faculty of observation is, one must sorrowfully admit, too often a result of studies conducted in the manner of English schools; but the method of education by travel is surely at least as old as the days of the obsolete Grand Tour; and educational journeys for children form part of the routine of many continental schools.

The short record of a family trip round the world is of a character with which the public is familiar: notes of the trivial incidents of life on board ship, little bits of history, occasional touches of moralising, and vivid impressions of what must have been a very enjoyable as well as a most instructive holiday. The route led by Gibraltar and Naples to Port Said, thence to Colombo, whence a considerable tour in Ceylon was made, on to Australia, Tasmania, New Zealand, Samoa, the Sandwich Islands, and home by the Canadian Pacific Railway and the Atlantic. The young people are indeed to be envied who have so magnificent an opportunity of educating themselves by seeing the world while still unstifled by scholastic cram.

A few slips are not to be wondered at. It is remarked of the Suez Canal that "larger undertakings of the same kind have been carried out since," the diversity in the use of Tacoma and Rainier (not *Ranier* as printed), as names of a mountain, is not correctly described; Morley is transposed to the wrong side of the Rocky Mountains, and Labrador and Newfoundland change places on the Strait of Belleisle. There is, unfortunately, no map; but if read with an atlas, this pleasantly written book should prove a valuable supplement to more formal geographies. H. R. M.

Wild Flowers, and other Poems. By James Rigg. Pp. 294. (Paisley and London: Gardner, 1897.)

IT is not within our province to express an opinion on the metrical merits of this volume. The author is evidently an ardent lover of nature, and of a poetic disposition. We have learnt, by sad experience, not to expect too much scientific accuracy from writers of verse; and the volume before us is not alone in its offences. Still, it does seem strange that the author should not have got some botanist friend to look over his proof-sheets; for by so doing he would have learnt that *Vaccinium europæa* (*sic*) is not the Latin name of the "blaeberry" (*sic*), nor *Stellaria minor* of the chickweed, nor *Pinus borealis* of the Scotch pine. The Latin names are constantly misspelt.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Mathematics used in Connection with Physics.

IT may seem ungracious for an author to reply to a review containing so many kind expressions as the one with which Prof. Ayrton has honoured my book on "Electricity and Magnetism" in your issue of November 18; nevertheless, I trust that you will permit me to make a few explanations and even corrections, if the word is permissible.

Since the reviewer states that "it is not quite obvious what is the object of giving" the mathematical introduction, I may state rather more fully than I was able to do in my rather long preface for what class the book was intended. The only class of students with which I come in contact at Clark University is composed of so-called "graduate students," that is men who have taken the bachelor's degree at a college, and are intending to undertake research. It is not generally known that this university was founded for the express purpose of encouraging such men, and consequently, alone among American universities (with the exception of the Catholic University in Washington), has no other students. The same class of students is, however, to be found in large numbers at all the larger universities, so that what I have to say is of general application. These students come to us from all parts of the United States and Canada, and I have had two or three from Europe, so that they have had very various training. They have been at college for four years or more, and have generally taught for awhile themselves. They may have studied the calculus for two years or less, so that although they all know "the meaning of a differential coefficient," and are able to integrate and differentiate with fluency, they are not Cambridge wranglers, and their ideas regarding continuity, convergence of series, definite integrals, and the like, are generally decidedly hazy, while they probably have no acquaintance with the calculus of variations, the theory of functions, and more difficult subjects. It was in order to have some of these matters of most frequent occurrence in a convenient place to refer to that I prefixed the introduction, not with the idea of giving a complete treatment, but to show the student some of the things he should certainly get up, and by means of foot-notes to show him where he could go further. In the numerous kind letters that I have received from teachers of physics in this country, I think all have especially commended the idea of this introduction. At any rate, I had so good an example as Maxwell, who thought it worth while to put a mathematical chapter at the beginning.

With regard to the suggestion that "possibly the students of Clark University, when listening to such lectures as are given in this treatise, have the physical meanings of the various mathematical processes explained to them," which the reviewer intimates would be desirable, I will say that these students have worked generally two years or more in a laboratory, making the usual measurements, and that it is hardly necessary to explain to them what a magnet is, or how a galvanometer is constructed. In order to cover the ground, it was necessary to condense, as the book was already larger than I intended.

Prof. Ayrton asks, "Is it correct to say that 'following the usage of the majority of writers, we shall denote' Laplace's operator (*I forbear* to write the signs of variation, which the printer has put for round *d*'s) ' by Δ,' seeing that many writers, including Thomson and Tait, use ∇^2 and Maxwell $-\nabla^2$?"

I was rather careful to find this out when writing the passage, and I quote only from the works which I have at hand. I may state that to the two authors named using ∇^2 might have been added the names of Lamb, Minchin, Routh, Basset, and Rayleigh, while the notation Δ is used by Mascart and Joubert, Duhem, Kirchhoff, F. Neumann, C. Neumann, Mathieu, Boltzmann, Helmholtz, Clausius, Drude, Picard, Jordan, Hertz, Klein, and by Poincaré, who calls it *la notation habituelle*. The notation Δ_2 is used by Lamé, Somoff, Boussinesq and Voigt, while Betti writes Δ^2. I did not say "the majority of English writers."

That Gauss's theorem "would be perfectly useless if gravitational, electric, and magnetic forces did not vary as the inverse square," I can hardly agree, seeing that it would be just as true, and would have applications to the flow of heat, hydrokinematics, geometry, and the theory of functions. It is just as well for electricians to remember that the world was not made for them alone.

The reviewer is certainly labouring under a misapprehension when he says "The statement of the general problem of electrostatics, as given at the beginning of § 135, is insufficient since, as pointed out, any number of solutions could be given to it." On the contrary it is explicitly pointed out, at the top of page 265, that there is but one solution, which is completely determined. It is comforting, however, to learn that "the method, however, which is indicated for the solution of the problem is correct, and leads in a neat way to the conception of coefficients of induction"; though the credit can hardly be taken by the present writer, the method being taken from Betti's well-known treatise given among the list of works made use of.

With regard to d'Alembert's principle, I will only say that for the purpose for which it is introduced, namely the deduction of the equations of motion of a system of particles, Hamilton's principle, &c., it seems to me that it makes no difference whether the internal forces appear or not. In any case I have said more about the principle than Kirchhoff, who merely writes down the formula, and Appell, who only says *qui signifie que, pour un déplacement virtuel arbitraire imprimé au point à l'instant, la somme des travaux virtuels de la force d'inertie et des forces reellement appliquées au point est nulle.* Practically the same statement is made by Thomson and Tait, and repeated by Tait in his small book on dynamics.

It seems to me that Green's function is hardly "divorced from its physical application" when it is stated that Green introduced it to solve certain problems in electrostatics. Its physical meaning as the potential of a certain electrification is also given.

The reviewer states that the analogy between electrical and magnetic phenomena is carried *too far* when the same letter is used for specific inductive capacity on some pages and for magnetic permeability on others. Also that "the beginner might expect to find μ instead of which he finds ϵ; the meaning, however, of this ϵ does not seem to be given." As a matter of fact, it is explicitly stated that μ is used where it refers indifferently to *either* the electric or magnetic quantity, while the meaning of ϵ is given in the next line to the one in which it first occurs, on page 509.

With regard to my "poking fun" at anything or anybody, I beg leave to assure Prof. Ayrton that his statement that "the fun is not intentional on the part of the author" is due to a misapprehension.

Finally, to the suggestion that "a course of 'Lectures on Mathematical Physics' may fitly contain explanations of the physical interpretations of the equations developed without running the risk of appearing to pander to the electrical contractor," it may be replied that much depends upon the point of view. To me the steam-engine or the dynamo are interesting as examples in thermodynamics or induction. I am well aware that this is not the usual view, nor do I suppose it ever will be. I need not conceal the fact that none of my students have ever become engineers. We have an excellent engineering school in our city (which, by the way, is Worcester, and not Webster, as your heading makes it), and we have no reason to try to duplicate the work done there. Some of its graduates have come to us, and have done good work in physics or mathematics. but they have dropped engineering. I say this, not with the slightest wish to disparage engineering or engineers, but to emphasise the fact that there are others to be considered as well.

A. G. WEBSTER.

Clark University, Worcester, Mass., December 15, 1897.

A New Single Picture Pseudoscope.

THE principle of the stereoscope is so well known that it is unnecessary to point out that two dissimilar pictures are required of a special character in order to produce the stereoscopic or solid effect. Consequently it may be imagined that to obtain a stereoscopic effect with a single picture is an impossibility.

It is clear that if the possibility exists a *true* stereoscopic combination would not result, but one which would approximate more or less closely to the truth.

Many devices have been brought out in the hope of giving a single picture a solid appearance, such for instance as a large convex lens. All these devices, however, fail to give the desired result. The illusion, so far as it goes, is simply a distortion of the original picture.

The nearest approach to the production of the stereoscopic effect from a single picture is by photographing the illustration with its plane inclined at an angle of the optic axis of the lens, first in one direction, and then again in the opposite direction; in which manner two dissimilar pictures are produced, which can be viewed with an ordinary stereoscope, and the result is by no means unsatisfactory. The process, however, is inconvenient.

For a long time past the writer has been experimenting with stereoscopy, and amongst other objects one has been to secure a stereoscopic effect with a single picture. This he has now succeeded in attaining in a comparatively simple manner.

If a stereoscopic slide is examined it will be found that each picture is compressed, so to speak, on the inner side, which is equivalent to saying that the central line of any one picture is shifted from the centre inwards, thus expanding one half of the picture and compressing the other half.

It therefore appeared to the writer that, if by some means a single picture could be made to give two images, each one compressed in a suitable manner and then viewed with the ordinary stereoscopic lenses, the solid effect should be produced, and such is the case.

The method is as follows:—A large deep cylindrical lens is taken and cut in two along the line where the lens is thinnest. Thus two wedges are produced, each having one side curved and the other side flat. If these two pieces are placed together, with the thick portions towards one another, and held at a short distance over any picture, the eyes will perceive an image of the illustration in each lens, and the pictures will be compressed in the manner already referred to.

All that is now necessary is to view these two images with ordinary stereoscopic lenses. One picture will result, as solid in appearance as if the ordinary stereo-slide had been employed.

The apparatus will be found of considerable use for looking at small photographic portraits, landscapes, &c., as well as engravings. The result is very pretty.

Naturally one class of picture must suffer under the operation; but as these are comparatively rare, there is an extended use for the instrument, which is called the Pseudoscope.

The pictures unsuitable are those which represent an object when placed very near the eyes, since the image produced by solid objects in each eye in such cases differ greatly; but this difference in the image is comparatively small after a distance of, say, 15 to 20 feet.

DAVID SALOMONS.

MAGNETIC OBSERVATIONS IN THE HARZ MOUNTAINS.

DR. ESCHENHAGEN has made an interesting series of magnetic observations at forty-two stations in the Harz Mountains.

The uncertainty of a declination observation was about 1', of the dip with two needles about 1'·2, and the probable error of the horizontal force was about ± 0·00010 C.G.S. units. As it was intended to compare the results with those of a survey of the same district in which the deviations of the plumb-line were determined, the stations were selected with reference to this fact, and also to the geological conformation of the country.

The magnetic disturbances and disturbing forces were determined by a method essentially similar to that employed in the survey of the United Kingdom. The results were not very definite in the northern part of the district examined, but a clearly marked "ridge-line," or locus of attraction on the north-pole of the magnet, was discovered in the south. In one part of this the vertical disturbing force nearly reached 0·00400 C.G.S. units. There are few stations in England and Wales where the disturbance is as large as this, though at Stratford-on-Avon it is exceeded by 25 per cent. At some places purely local attractions of very much larger magnitude were detected. Thus, on the Leistklippe the dip was altered by 11', and the vertical disturbing force was 0·04224 C.G.S., or one-tenth of the whole vertical force. No such remarkable effects were observed near the principal granitic masses, such as the Brocken.

The fact that the magnetic ridge-line lies to the south of these is explained by the hypothesis that the granitic mass, of which the Brocken is the upper end, extends underground in a direction inclined to the vertical, and running from the surface towards the south. This view is, in the opinion of Dr. Eschenhagen, consistent with the geological facts. As, however, the granite is but slightly magnetic, it is also necessary to suppose that the heavier, more magnetic granite, lies deep, and is only brought near to the surface at a few points such as those at which the greatest local disturbances occur.

The local deviations of the plumb-line were deduced from observations made by the Royal Prussian Geodetic Institute. To the north of the mountains the plumb-line is deflected to the south; from the south an attraction towards the north is detected. The line of no deviation is to the south of the Brocken, and runs nearly parallel to, but about 10-12 km. north of, the magnetic ridge-line.

The remarkable result is therefore attained that (1) geological evidence, (2) the magnetic needle, and (3) the plumb-line all point to the conclusion that the heavier rocks lie some distance to the south of the chief visible masses of granite.

Dr. Eschenhagen is careful to point out that it is unlikely that a similar agreement would be attained in every place where similar experiments might be carried out, as the rocks of greatest density are not necessarily magnetic. None the less, his observations make it probable that the magnet, the pendulum and the plumb-line may add much to our knowledge of the details of the constitution of the crust of the earth; and his survey of the Harz Mountains is one of the most striking attempts which have yet been made to combine the results of magnetic and geodetic surveys.

A. W. R.

THE JOURNAL OF ANATOMY AND PHYSIOLOGY.

NEARLY nine years ago, on the occasion of the coming of age of the above-named Journal, we directed attention (NATURE, vol. xxxvii. p. [illegible]) to its association, as a medium of publication, with the then newly established "Anatomical Society of Great Britain and Ireland." Since that time the connection between the two has been maintained, much to the advantage of the Journal, for not only have the "Proceedings" of the Society materially improved and increased in bulk and importance, but many of the leading papers which have appeared in the body of the Journal have reached it through the mediation of the Society, while in the latter's annual reports of its "Committee of Collective Investigation" there have been contributed results of great service alike to the scientific and surgical anatomist. Owing to the death of the founder of the Journal and main supporter during its earlier years, the beloved and universally respected Sir G. Humphry, a reconstitution of the staff of its "conductors" was recently decided upon, and with the issue for October last a new series was accordingly commenced, Profs. Sir W. Turner and J. G. McKendrick, so long associated with its success, announcing that for the future they would be assisted by Profs. D. J. Cunningham, A. Macalister, and G. D. Thane. There has just reached us the second (January) part which has appeared under these new auspices. During the years which have elapsed since our previous notice was written, three of the five present conductors of the Journal have been presidents of the Anatomical Society, while Prof. Macalister, having been on November 26 elected to that office, now combines the two functions. And during the same period the Anatomical Society undertook the preparation, and the conductors of the Journal the publication, of a couple of analytical indexes to its first thirty volumes, entrusting the task to Mr. A. W. Kappel, the efficient librarian of the Linnean Society of London, who has carried it out with conspicuous success. Society and Journal have thus become more and more closely connected, and to what extent may be gathered from the fact that of the thirty-three papers which make up the body of the first two parts of the new series, fifteen were read at the Society's meetings. Of these, the papers by Prof. D. J. Cunningham and Dr. Elliot Smith on the anatomy of the cerebral cortex and fornix stand pre-eminent, as important communications by leading investigators, who with Symington and others have kept this rapidly developing department of laborious research fully abreast of the continental standard set by von Kölliker, Edinger, Ziehen, and those who have followed in the wake of Golgi and y Cajal. Dr. Elliot Smith's monographs are indispensable to the comparative neurologist, and they amply fulfil the expectation raised by his early investigations in Australia, and justify the graceful comment paid by Sir W. Turner at the summer meeting of the Anatomical Society, held in Dublin in June last, at which one was hurriedly read. Beyond this, the second issue in the new series of the Journal is especially noteworthy for a paper by Prof. Symington upon the thymus gland in Marsupials, about which little indeed is known, and for the first part of one by Dr. D. A. Welsh upon the parathyroid glands, both being exceedingly welcome now that current work upon the ductless- and blood-glands is revolutionising our knowledge and conceptions of these remarkable organs. Noteworthy also is the completion in the same part of a lengthy treatise by Dr. W. McDougall upon a theory of muscular contraction, since by comparison with a remarkable paper by Prof. Rutherford, side by side with which it has for the most part appeared, it opens up fresh themes for controversy upon this interminable topic, which show at least that the last word has not been written concerning it, and that there is sore need of its attack on other than morphological lines. Returning to the first part, we note a paper by Mr. F. J. Cole on the urinogenital system of the male guinea-pig, which for thoroughness of investigation and exhaustive literary research is worthy the standard he adopted in a recent paper on the nervous system of the chimæroids, and the very interesting announcement by Prof. Disse, of Marburg, that the olfactory nerve fibres in the chick arise from cells situated in the epithelium of the olfactory pit, and by Prof. Leboucq, of Ghent, that in the full-grown fœtus of a *Vespertilio* the fourth digit of the manus is tetraphalangeate.

Of the remaining papers one only calls for special comment, viz. that "On the anatomy of *Macropus rufus*," by Prof. Bertram Windle and Mr. F. G. Parsons, since it reveals some strange contradictions both within its own limits and by comparison with the afore-mentioned paper by Symington. It contains a great deal by way of careful and detailed anatomical description which, in correlation with similar papers which its authors have published elsewhere, ought to be of service for reference. Under the heading "Digestive System," however, they have described and figured the liver on one page as destitute of a left central lobe, the lobe present on that side being regarded as a left lateral, while on the very next page the latter is said to be absent. Their first conclusion is based on the relationships of the falciform ligament, unquestionably the only structure of real morphological value for the purpose, and they introduce some pertinent criticism of the methods of other anatomists. All the more remarkable, therefore, their account of certain glands, as said to exist in the "fœtus" (strictly a pouch specimen). On p 132 there is given a processed illustration, little resembling anything in nature, with an accompanying description of glandular structures regarded as "sublingual" and "extra-salivary." That the former are merely the ordinary sub-maxillary glands, there seems no manner of doubt. Concerning the latter, we are assured that "histological examination proved that they were salivary in nature." Great though the backward extension of the salivary glands in some mammals, nothing at all approximate to the remarkable condition here alleged has hitherto been observed, and sufficient is recorded by the authors of the detailed relationships of the so-called "extra salivary" glands to render it tolerably certain that they are but cervical thymus, a conclusion borne out by the authors' confession that they "did not succeed in tracing the termination of their ducts," and by comparison of the descriptions and figures of the neck glands in *M. giganteus* given by Symington, as he justly points out (p. 283). The brief statement which we cite concerning the histology of these glands is wholly insufficient. If they be really salivary, for so extraordinary a condition at least a figure and full details of microscopic sections should have been furnished in absolute proof. While we await with interest further investigation as to the real nature of these, we cannot allow the statements concerning the liver to pass without further comment. Leading anatomical journals other than that now under review might be cited in which inaccuracies unpardonable at times appear. Authors, when inexperienced, will write extraordinary things; experienced authors still more extraordinary. And surely the rendering of Nathusius's well-known name (p. xxix. Suppl.) as "Nathenius," is a matter which the editors, if not the author, should not have allowed to pass. The first two parts of the new issue of the Journal, as a whole admirable and encouraging, give excellent promise for the future, if only the conductors will declare themselves responsible editors and a proper coordination between authors and editors be assured.

GEOLOGY AND SANITARY SCIENCE.[1]

THIS memoir is a new departure on the part of the Geological Survey, being devoted only to applied geology, to questions which have for a long time caused the flow of a steady stream of inquirers to Jermyn Street. It shows how useful is some knowledge of geology to the proper understanding of many matters that are ever cropping up, privately in such things as the choice of a site for a dwelling, and publicly in such as water-supply for a district.

The extent of the district treated is shown by the excellent chromolithographed map, and may be understood from the following list of the border-towns, with London in the centre:—Chesham, Amersham, Beaconsfield, Windsor, Guildford, Dorking, Reigate, Sevenoaks, Gravesend, Billericay, Chipping Ongar, Epping and St. Albans. The colours differ largely from those used on the Survey maps, and the map differs from the lately issued Index Map (on the same scale, four miles to an inch) in showing the various divisions of the Drift; so that there are thirteen colours, besides a blank for Alluvium.

A short description is given of the general structure of the London Basin, with parts of its borders, and then (pp. 7–25) a more detailed account of the beds dealt with, from the Made Ground of London down to the Hastings Beds of the Weald; thus going a little beyond the area of the map, on the south, in which the last are not shown. These are grouped, not in the usual geologic way, but according to character; all gravels and sands being under one heading, all clays under another, with an intervening "mixed sub-soils" for those divisions that decline to be distinctly one thing or another. Under each of the many sub-headings the sanitary aspects of the beds are noticed. In the map the index of colours is grouped in three series, clayey, gravelly and sandy, with Alluvium detached at the top, and Chalk at the bottom.

---

[1] "Memoirs of the Geological Survey. Soils and Sub-soils from a Sanitary Point of View; with especial reference to London and its Neighbourhood." By H. B. Woodward. Large 8vo. Pp. vi + 58; folding geologic map (13 colours).

In the rest of the memoir a purely sanitary arrangement is adopted, under four heads, the first being that of the sub-soil with reference to sites for houses (pp. 27–32). The way in which not only the character of the beds, but also their thickness, position, and mutual relations affect the suitability of ground for building-purposes is enforced, and the causes of contamination of porous sub-soils are discussed: even gardens are not neglected.

Secondly, water-supply and drainage are treated (pp. 33–39). After noticing the supply of London, the question of rural water-supply is taken, the causes of contamination of shallow wells and the danger of "dead wells," used as receptacles for sewage, &c., being described. Then we have sanitary considerations in regard to the situation and surroundings of houses (pp. 40–45), under which head subjects other than geologic are referred to, such as surface-drainage, fog, sunshine, rain, wind, floods.

The troublesome question of cemeteries fittingly comes last (pp. 46–48), and the author concludes that "an isolated tract of elevated ground, where sands and sandy loams, or sandy and loamy gravel, of considerable thickness, rest on clay also of considerable thickness, offers the most desirable site," which, however, is qualified by the addition that "probably a sandy and calcareous loam is the best material for a graveyard." However, the difficulty is to get such desirable sites! The fitting conclusion is a list of the cemeteries in and near London, with the beds on which they are placed, by means of which people who are thoughtful of their latter end can select the geologic formation in which they would like to be buried.

The long index (ten pages), is really more than an index. It is not limited to giving the pages of reference; but also notes, by figures in another type, the height of the various places above Ordnance datum, and, by means of letters, the beds on which the places are—an ingenious and useful novelty.

Although this is the first Geological Survey memoir devoted to sanitary matters, it should be remembered that stores of information that is useful from a sanitary point of view are to be found in many of those memoirs, especially as regards wells and water-supply.

This work should have a ready sale, as it is written in such a way as to be useful to the ordinary inquirer, and of interest to any intelligent reader; but the price (2*s*. 6*d*.) is rather high, presumably on account of the map. It is to be hoped that the author may ere long have to prepare a new and enlarged edition, and that the success of the present venture may lead to other work of the same sort being undertaken.

W. WHITAKER.

PROFS. C. RUNGE AND F. PASCHEN'S RESEARCHES ON THE SPECTRA OF OXYGEN, SULPHUR, AND SELENIUM.[1]

IN the above paper Profs. Runge and Paschen have extended their important investigations to the spectra of oxygen, sulphur and selenium, and have discovered in the low temperature spectra of these elements a number of series which are very similar to those previously found for other elements. The principal characteristics of these series are too well known to need any further explanation; they may be represented by Kayser and Runge's original formula,

$$N = A - \frac{B}{n^2} - \frac{C}{n^4},$$

where N is the wave frequency and n takes up the values 3, 4, 5 . . . for the different lines of the same series. In the present cases n^4 may be with advantage replaced by n^3. We may with equal accuracy take Rydberg's formula,

$$N = A - B(n + \mu)^{-2},$$

where A, B, μ are the three constants. In the spectrum of oxygen which goes by the name of "compound line spectrum," and which Piazzi Smyth has shown to be chiefly made up of close triplets, Runge and Paschen show that these triplets arrange themselves in two series, having approximately the same convergence frequency. The difference in the curve numbers of the components being the same for each triplet, they have all the characteristics of the "Nebenserien" or "associated series," as I propose to call them, because they always occur in groups of two. The formulæ for the strongest lines of the triplets in Rydberg's form is

1st assoc. series: $23207.96 - 110396\,(n - 0{\cdot}02148)^{-2}$
2nd „ „ $23200,63 - 109011\,(n - 0{\cdot}24127)^{-2}$

Rydberg has given a law according to which the principal series may be calculated from the associated series, with sufficient approximation to identify the lines belonging to it in the present instance. Only two triplets belonging to it have been found; the first in the extreme red has a wave-length of 7776 for its strongest lines, and the second, photographed by Runge and Paschen for the first time, has a wave-length 3948. In addition to the triplets, the authors have discovered a number of doublets which can also be grouped into two associated series, having the equations

$$21205,56 \cdot 109366,7\,(n - 0{\cdot}16191)^{-2}$$
$$21211,11 - 110346,7\,(n - 0{\cdot}01093)^{-2}$$

and the principal series belonging to this group is probably represented by two lines at wave-lengths 4368, 5, and 3692, 6, the former being one of the strongest lines of the compound line spectrum.

The result of this investigation of the oxygen spectrum is, that it shows two sets of associated series similar to that found in the case of helium, and that therefore the spectroscopic evidence that helium is a mixture of two gases no longer holds. There is very little doubt that the oxygen spectrum is represented among the Fraunhofer lines; almost conclusive evidence in favour of this being given by the first triplet of the principal series, which falls at 7776 in a portion of the solar spectrum which is comparatively free from lines. The beautiful photographs of Higg show at this place a triplet the components of which have exactly the right difference in frequency.

Profs. Runge and Paschen also investigated the spectra of sulphur and selenium, and discovered spectra which correspond to the compound line spectrum of oxygen. The spectra consist chiefly of triplets which may be arranged in a group of associated series; and there are also indications of the existence of two principal series in each case. The authors apparently considered these spectra as due to the elements, but they have only been able to obtain them in the presence of oxygen. Further investigation is therefore required to show that they are not really oxide spectra. Should this prove to be the case it would be a matter of some importance and great interest, for it would show that we must consider the compound line spectrum of oxygen as due to a compound molecule, an "oxide of oxygen" similar in constitution to the oxides of sulphur and selenium which give the analogous spectra.

In conclusion, I may add a few remarks as to the relative merits of Rydberg's and Kayser and Runge's equations. The greater simplicity in form of

$$N = A - \frac{B}{n^2} - \frac{C}{n^4}$$

adopted by Kayser and Runge, and the ease with which the constants may be calculated would, independently of other considerations, lead us to give the preference to this form. The advantage is not, however, great, and disappears when we have to distinguish cases where we must substitute n^3 for n^4. The reason why I prefer Rydberg's form at present lies in the fact that it adapts itself better to bring out the regularities as well as the irregularities of distribution of the lines independently of any special form of equation. To show this we may write Rydberg's equation in the form

---

[1] *Wiedemann's Annalen*, vol. lxi. p. 641.

$$\frac{n+\mu}{\sqrt{B}}=\frac{1}{\sqrt{A-N}}.$$

The convergence frequency, A, may be determined by some graphical process if a sufficient number of lines have been observed, and the law of formation of a spectroscopic series may therefore be expressed as follows:

The inverse square roots of the difference between the convergence frequency and the frequency of successive lines are very approximately in arithmetical progression. If we wish to determine how far any series conforms to this law, we may in the first place calculate the right-hand side of the above expression with some approximate value of A. Systematic deviations from arithmetical progression may then be corrected by a small change, δA producing a difference $\frac{\delta A}{\sqrt{(A-N)^3}}$ in the numbers. But it will nearly always be found that there are some outstanding deviations which cannot be corrected for in this way. The value of B is found at once from the arithmetical progression successive numbers differing by $\frac{1}{\sqrt{B}}$. I have found this method of testing the series and calculating the constants very useful, and hope on some other occasion to return to it.

ARTHUR SCHUSTER.

UNDULATIONS IN LAKES AND INLAND SEAS DUE TO WIND AND ATMOSPHERIC PRESSURE.

IT is generally known that considerable variation takes place in the level of the surface of the water in lakes and inland seas owing to the effect of the wind in gales and during stormy weather. The minor undulations which occur at more regular intervals have not attracted the same observation, and the cause of these is still a matter of some uncertainty. In the large lakes in America, fishermen and boatmen have learnt to regard these undulations as storm warnings; and on the coasts of Europe, the rollers which break on the shore in calm weather are looked upon as indicative of a coming storm. Thus, in the Bay of Biscay frequently during the autumn and winter in calm weather a heavy sea gets up and rolls in on to the coast four-and-twenty hours before the gale which causes it arrives, and of which it is the prelude In this case the wave action, generated on the other side of the Atlantic by the wind, travels at much greater rate than that of wind, and thus gives timely warning of the coming storm. So also on the opposite side of the Atlantic, on the coast between North Carolina and Cape Hatteras, the currents, which are there largely governed by the wind, begin to run strongly several hours in advance of the wind which causes them. In summer a change of the current from north-east to south-west is always taken as a true indication of an approaching north-east wind.

The effect of gales on tideless seas and lakes is so marked as to cause frequently considerable inconvenience and anxiety to mariners. Thus, in the Caspian Sea a gale will raise the water on one side 6 feet and depress it on the other as much, making a total difference of level of 12 feet.[1] In the Baltic easterly gales will alter the level upwards of 8 feet. In Lake Erie[1] depressions and elevations of from 2 to 4 feet are common, while occasionally heavy gales have produced a difference of level of upwards of 15 feet. Almost invariably about the time of the spring equinox strong gales occur from the east, raising the water from 4 to 6 feet at the west end of the lake, and depressing it to a similar extent at the east end, making a total difference of from 8 to 12 feet. About the time of the autumn equinox gales from the west lower the water 7 to 8 feet at the west side, and raise it 5 to 8 feet at the east end, making a difference from the normal level of from 12 to 16 feet. An illustration is given by Mr. Blunt, the engineer, who reported on the subject for the United States Commission as to the way in which the navigation of the lakes and of the rivers connected with them is affected by storms acting on the surface of the water. A steamer which had to make a trip down the river found the water at the pier from which she started, five miles from the mouth, had receded to 7½ feet below the normal level. In the river, flats were showing where a few days before they had found 8 feet of water. In the middle of the bay a large dredger was aground where there ought to have been 17 feet of water.

In addition to these larger oscillations, there are also minor undulations which occur at varying intervals, the largest period for a complete oscillation not exceeding half an hour, and the alteration in the level of the water not more than from three to four inches. The phenomena had been noted by Duillier on the Swiss Lakes in the middle of the last century, the name locally given to them being *Seiches*. In 1804 Vaucher also investigated the matter and published an account of his researches, his experience being that they were common to all the lakes; that they recurred at all seasons of the year, but most frequently in spring and autumn, the greatest oscillation, however, occurring in the summer; and that the intervals between the oscillations did not exceed twenty to twenty-five minutes, and more frequently less.

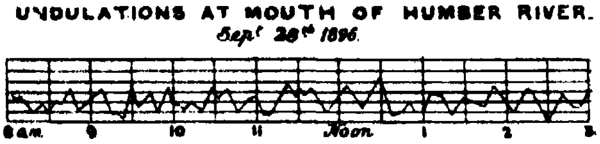

FIG. 1.

A few years since the writer had occasion to investigate the oscillations which took place in one of the Norfolk Broads, and which were taken as showing that the water was tidal. It was found that variations of from half an inch to two and three inches in the level of the water took place periodically, and at times when the atmosphere was calm. Observations spread over a considerable time proved that these undulations were not coincident with the rise and fall of the tides, and that they had no direct connection with the ebb and flow in the river with which this Broad was connected.

The character of the undulations on Lake Superior has been investigated by Mr. Napier Denison, and the results communicated to the Canadian Institute in February 1897, in a paper entitled "The great lakes as a sensitive barometer." For the purpose of tracing these curves Mr. Denison had two self-recording gauges constructed, one being fixed at the mouth of the river Humber, and the other at the Burlington Canal. The results of one day's reading at the mouth of the Humber are shown in Fig. 1, which is sufficient generally to illustrate the result of the readings obtained, and as showing the rapid undulations upon the lakes during light winds and fine weather preceding a severe storm. (The divisions in the above diagram represent inches.) The undulations generally vary from three to four inches at intervals of from fourteen to eighteen minutes. The centre of the storm which caused these oscillations was over the State of Florida, 1300 miles distant. This storm centre travelled slowly but directly to the lake region, where it caused a severe gale. These lake undulations are found to be of a more sensitive character than the indications of approaching storms given by the barometer. Mr. Denison is of opinion that these oscillations are due to the action of atmospheric waves or billows in passing over the surface of the lakes, which tend to form minute undulations upon the surface corresponding in length to these billows, and becoming magnified when they reach narrower and shallower portions, until finally they assume the proportions recorded upon the instrument.

---

[1] "Tidal Rivers," chap. v. (Longmans, Green, and Co.).

[1] Report of Deep Waterways Commission, U.S.A. (Washington, 1897).

Attention has also recently been directed to the minor undulations which occur in tidal waters by Mr. W. Bell Dawson, the Government surveyor engaged in the tidal survey of the Gulf of St. Lawrence, in a paper presented to the Royal Society of Canada in May 1895, entitled "Notes on secondary undulations." These undulatory disturbances in the regular rise and fall of the tides in the Gulf of St. Lawrence are plainly marked on the records of the self-registering tide gauges, their magnitude being in proportion to the amplitude of the tides. Similar undulations have also been observed in the Mediterranean at Malta. The illustration (Fig. 2, taken from Mr. Dawson's paper) shows the character of these undulations at high and low water in part of the Bay of Fundy, on tides having an amplitude of from 17 to 19 feet.

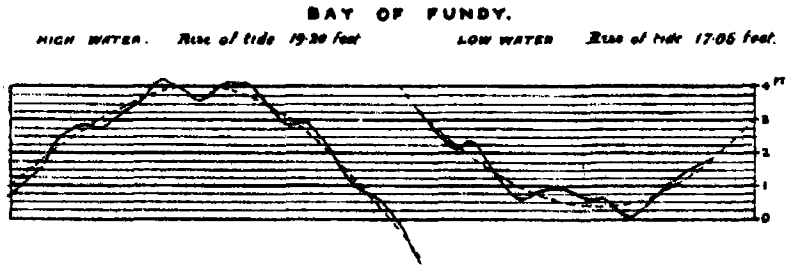

FIG. 2.

W. H. WHEELER.

NOTES.

THE meeting of the Royal Society on Thursday, February 24, will be devoted to a discussion of the "scientific advantages of an Antarctic Expedition." The debate will be opened by Dr. John Murray, F.R.S., of the *Challenger*.

PROF. L. CREMONA, professor of higher mathematics in the University of Rome, has been elected a Correspondant of the Paris Academy of Sciences, in succession to the late Prof. Sylvester.

H.R.H. THE PRINCE OF WALES has been graciously pleased to accept the post of Patron of the fourth International Congress of Zoology, to be held at Cambridge next August.

A MEETING will be held in Manchester on February 16 to take into consideration such steps as may seem desirable to assist the Executive Committee in making the Zoological Congress this year thoroughly successful. The Literary and Philosophical Society have put their rooms at the disposal of the meeting, and Mr. J. Cosmo Melvill will take the chair at 5 o'clock on that day. This appears to us to be an excellent movement, and one worthy of imitation in other large centres. Zoologists who propose to be present should communicate with Prof. Hickson, F.R.S., at the Owens College, Manchester.

MR. THOMAS H. BLAKESLEY has resigned his seat at the Council Board of the Physical Society. He is, therefore, no longer hon. secretary of that Society.

IT has been decided to publish, under the auspices of the Physical Society and the Institution of Electrical Engineers, a series of abstracts of English, American, and foreign papers on physics and electrical engineering.

THE Harvard University, Cambridge, Mass., has invited Dr. Hans Reusch, Director of the Norwegian Geological Survey, to give two series of lectures—one on "Vulcanism," the other on "the Geology of Scandinavia." Dr. Reusch will return to Christiania in June.

AT the annual meeting of the Royal Microscopical Society on Wednesday, January 19, the President, after reviewing the progress in microscopical science during the past year, gave for his address an account of the manner in which achromatic doublets and triplets were practically calculated. The President explained by drawings on the blackboard the general scope of the paper, which, owing to its mathematical treatment, could not be read verbatim.

THE death is announced of Dr. Samuel Newth, author of "A First Book of Natural Philosophy," which has had a very large sale, and "The Elements of Mathematics, including Hydrostatics." In 1855 Dr. Newth became professor of mathematics and ecclesiastical history in the New College, St. John's Wood, and succeeded Dr. Halley as principal of the College in 1872, retiring from this post in 1889.

WE learn from *Science* that, at the meeting of the Corporation of Yale University on January 13, Prof. O. C. Marsh, professor of palæontology, formally presented to the University the valuable scientific collections belonging to him, now deposited in the Peabody Museum. These collections, six in number, are in many respects the most extensive and valuable of any in America, and have been brought together by Prof. Marsh, at great labour and expense, during the last thirty years. They include collections of vertebrate fossils, fossil footprints, invertebrate fossils, recent osteology, American archæology and ethnology, and minerals. The palæontological collections are well known, and were mainly secured by Prof. Marsh during his explorations in the Rocky Mountains. They include most of the type specimens he has described in his various publications. The collection of osteology and that of American archæology are also extensive and of great interest. The present value of all these collections makes this the most important gift to natural science that Yale has yet received. The President and Fellows of Yale accepted Prof. Marsh's gift by a unanimous vote, and expressed their high appreciation of his generosity to the University.

AMONG the papers to be read at forthcoming meetings of the Society of Arts are the following:—Ordinary meetings (Wednesday evenings, at eight o'clock): February 23, children's sight, by Mr. R. Brudenell Carter; March 2, kites, their theory and practice, by Captain B. F. S. Baden-Powell; March 9, Linde's method of producing extreme cold and liquefying air, by Prof. J. A. Ewing, F.R.S.; March 16, the recent history of paper-making, by Mr. Clayton Beadle; March 23, the preparation of meat extracts, by Mr. C. R. Valentine; March 30, telegraphy across space, by Prof. Silvanus P. Thompson, F.R.S. Indian Section (Thursday afternoons, at 4.30 o'clock): February 17, the plague in Bombay, by Dr. Herbert Mills Birdwood; March 31, the earthquake in Assam, by Mr. Henry Luttman-Johnson. Foreign and Colonial Section (Tuesday afternoons at 4.30 o'clock): February 15, the goldfields of Klondike and British Columbia, by Mr. W. Hamilton Merritt. April 5, the sugar industry in the West Indies, by Mr. T. R. Tufnell. Cantor Lectures (Monday evenings, at eight o'clock): Prof. W. Noel Hartley, F.R.S., the thermo-chemistry of the Bessemer process (three lectures); Dr. D. Morris, C.M.G., india-rubber (two lectures); Prof. Carus Wilson, electric traction (four lectures).

A FEW particulars with reference to the late Dr. George Henry Horn, President of the American Entomological Society, are given in the *Entomologist's Monthly Magazine*. Dr. Horn was born April 7, 1840, in Philadelphia, and died November 24, 1897. He graduated in medicine in 1861, and from 1862 to 1866 was surgeon in the U.S. army. Subsequently he established himself as a physician in Philadelphia, and had an extensive practice. Before he graduated he published papers on recent and fossil corals, but eventually turned his attention entirely to North American *Coleoptera*, as a pupil of, and fellow-worker with, Leconte, until the death of the latter in 1883, and afterwards on his own account. It has been said that if the death of Leconte was a severe blow to North American coleopterology, that of Horn is probably greater. His first entomological paper was published in 1860, and was followed by others (jointly or separately) to the number of about 150, appearing almost entirely in America, but he worked out the *Eucnemidæ* for the "Biologia Centrali-Americana." As already announced, his collections, and a sum of money, have been left to the American Entomological Society, of which he had been long President.

PROF. DAVID P. TODD, Director of Amherst College Observatory, Amherst, Massachusetts, U.S.A., has nearly completed a bibliography of eclipse research to join on with Ranyard's classic work published many years ago in the *Memoirs* of the Royal Astronomical Society. He would be glad to receive copies of papers and titles of works and articles published since 1875.

THE Lincolnshire Science Society, the establishment of which was referred to in NATURE of December 30, 1897, should apparently have been christened the Lincoln Science Society; for a prospectus just received shows that a Lincolnshire Naturalists' Union has been in existence several years. There is hardly room for two county Societies having the same aims and objects, and the establishment of the new Society cannot but have a prejudicial effect upon the older Union, which ought to represent the combined forces of the different local societies in Lincolnshire. For the spirit of competition to enter into the matter at all is a mistake, and if the two organisations do not arrive at a concordat, the work of one will prejudice rather than assist the work of the other. It appears that the Lincolnshire Naturalists' Union initiated a scheme for the formation of a County Museum before the new Society took up the matter.

IN the last number of the U.S. *Monthly Weather Review* (October 1897), the editor draws attention to a proposal for establishing a meteorological station on Satulah Mountain, North Carolina, at an altitude of about 5000 feet. The summit of the peak is fairly level, and, with the exception of about a quarter of a mile, is accessible by vehicles. Prof. Abbe points out that a continuous record at the summit would undoubtedly contribute to the elucidation of some interesting meteorological problems, but that in view of the many unsuccessful attempts to maintain self-recording instruments in isolated places, watchful observers would be necessary. Systematic observations are being made at great elevations by means of balloons and kites, and these efforts may be usefully supplemented by renewed attention to the establishment of mountain stations.

AT the meeting of the French Meteorological Society on January 4, M. Moureaux made an important communication on the results of a mission entrusted to him by the Imperial Geographical Society of St. Petersburg with reference to the magnetic exploration of the Government of Koursk. The whole area of this province is intensely disturbed, and the differences between theory and observation are so great that it is not possible to draw isomagnetic lines. At two points situated about 450 yards apart the declinations are -11° and $+45^\circ$. In one district the declination at two stations about a mile and a quarter apart varied from -34° to $+96^\circ$. The dip ranged from 48° to 79°, and the horizontal component reached 0·59, whereas the maximum normal value of this element in the equatorial regions is below 0·40. From these observations it results that the magnetic force in that locality is as great as it would be in the immediate vicinity of the magnetic poles. So far as is known at present, there is nothing near the surface of the ground to cause these anomalies.

THE tracing of the pretty curves formed by compounding pendulum vibrations of different periods is a fascinating pastime of which we were beginning to believe the resources were pretty well exhausted. Prof. Charles Schlichter, of Winconsin, has, however, discovered "fresh woods and pastures new" by extending the method to space of three dimensions, and representing, by the aid of the stereoscope, the resultant of harmonic motions of three frequencies in three different directions mutually at right angles. To do this, Prof. Schlichter attaches a miniature electric lamp to the bob of a Blackburn pendulum vibrating in a horizontal plane, and photographs the tiny speck of light by means of a stereoscopic camera attached to a pendulum which swings in a vertical plane about a horizontal axis through the optical centres of the lenses. This last pendulum gives the third vibration-component. When the diagrams are viewed through the stereoscope, the curves spring out into relief like bent wires; their forms for many of the higher ratios, such as 5 : 6 : 9 or 5 : 8 : 9 being very striking.

EXPERIMENTS on the action of Röntgen rays on vegetable life have hitherto mostly led to negative results; but Signor G. Tolomei, writing in the *Atti dei Lincei*, is led to the conclusion that their action is identical with that of light. On exposing to the action of Röntgen rays branches of *Elodea canadensis* immersed in water charged with carbonic anhydride, evolution of bubbles took place as in the presence of sunshine or electric or magnesium light. The same similarity was observed in the effects on the lower vegetable forms, both Röntgen rays and light causing retardation in the absorption of oxygen by *Mycoderma aceti*, and in the evolution of carbonic anhydride by Saccharomyces. Again, in their action on *Bacillus anthracis* the Röntgen rays behave in the same way as sunshine, but in a minor degree; when a gelatine film was exposed for twenty-four hours to the radiations from a Crookes' tube, with the interposition of a zinc screen having an X-shaped aperture, the letter appeared transparent on an opaque background. That the action was due to destruction of the germs, and not to the generation of any toxic quality in the agar, was proved thus: when a sterilised film was partially exposed to the rays, and subsequently brought into contact with a stratum of dried spores, the spores began to germinate all over the film; but when the stratum of spores was exposed to the rays, the screen with the letter X being interposed, and the film subsequently brought into contact with them, only those spores which had been protected from the Röntgen rays developed, and the letter X was distinctly seen. Signor Tolomei attributes the previous failure to obtain such effects to the short duration of the exposures.

A LENGTHY report of the Committee, appointed by the Academy of Science and Literature at Montpellier, to inquire into the alleged vision through opaque objects, appears in *La Semaine Médicale* (January 19). The Committee prepared three letters, the contents of which could not be known to them, by writing words and numbers on sixty-four cards, placing them two and two into envelopes, and selecting three of the thirty-two envelopes haphazard; these three were carefully sealed. One envelope was sewn into the coat, another placed in the pocket of a member; the third, along with half an exposed photographic plate, was wrapped in many thicknesses of paper and placed in a box, which was also sealed. At Narbonne the box containing the envelope and plate was placed on Dr. Ferroul's table, since that was the usual position of the documents which had already been read by Mlle. X. The Committee then walked to Mlle. X.'s abode, about 300 metres from Dr. Ferroul's house. Mlle. X. did not succeed in reading the contents of the envelopes carried by the members of the Committee, and at first no success attended attempts to describe the contents of the sealed box. About an hour and a half after the commencement of the séance, during which time Mlle. X.'s sister passed to and fro, and Mlle. X. herself left the room on more than one occasion, the contents of the box were more or less correctly described. On re-examining the box the Committee came to the conclusion that it had been opened, and on developing the contained piece of photographic plate along with the other part, the former piece was fogged, although the latter developed perfectly.

The British Medical Journal of January 22 contains a reprint of the special inquiry on the relative efficiency of certain kinds of water filters which has been carried out for the *Journal*. Many of the conclusions arrived at are by no means encouraging; for example, an examination of the portable filters supplied for Army Field Service revealed the fact that not one of these afforded any protection against water-borne disease; that, on the contrary, "they would tend to increase rather than diminish the risk incurred by those making use of them, since when such filters had once been charged with contaminated water they would continue for some time afterwards to discharge the disease germs into the 'filtered' water." This is a very serious matter, and which, considering the numbers of cases of dysentery which have already occurred in the present Indian frontier war, might well demand the immediate attention of the Army Medical Department. The filter of the future remains as yet, it would seem, "a castle in the air"; where efficiency is procured, the rate of filtration is often such as to preclude it from practical use. It appears, however, likely that diatomaceous earths or natural stone will be generally preferred to denser media such as porcelain, these three being, amongst the materials at present in use for filters, the only ones which apparently supply an efficient filtering medium. The same number of the *Journal* contains a communication by E. H. Hankin on "a simple method of checking cholera in Indian villages," which consists in treating the wells in an infected district with potassium permanganate, a sufficient quantity being added in each case to give a pink colour lasting for several hours to the water. This plan appears to have produced favourable results in combating cholera outbreaks, and in some places even the natives have been induced to disinfect their wells by its means.

THE immense lava-sheets that cover an area of some two hundred thousand square miles in the Deccan of India have been looked upon as the grandest example of vulcanism in the world; but an even more extensive outpouring of similar material must formerly have been evident in the northern hemisphere, if we accept the conclusions reached by Messrs. Newton and Teall from a study of the geological collections made in Franz Josef Land by the Jackson-Harmsworth Expedition (*Quart. Journ. Geol. Soc.*, December 1897). That archipelago is formed of the fragments of an ancient basalt-plateau which must have stretched far beyond its present limits. Similar igneous rocks are found in Spitsbergen, Jan Mayen, Iceland, Greenland, the Faeroës, the Hebrides and North Ireland; and the authors are inclined to regard all these areas as the isolated fragments of a formerly continuous land-area, the greater part of which has sunk to form the northern portion of the North Atlantic Ocean. The period of this outpouring of lava was probably the end of Cretaceous and beginning of Tertiary times. This period seems to have been distinguished by similar occurrences in other parts of the world, for the great lava-flows of the Deccan and of Abyssinia are of the same age.

PROF. A. RICCÒ contributes to the latest *Bollettino* of the Italian Seismological Society an account of the Geodynamic Observatory of Catania, founded in 1891, and now one of the best equipped in Italy. It is situated beneath the astrophysical observatory, in the cellar of the former Benedictine convent. The principal instrument is one of Cancani's great seismometrographs, consisting of a pendulum 25·3 metres long and a mass of 300 kg., whose movements are magnified twelve and a half times, and recorded by two pens on a strip of paper moving at the rate of 60 cm. an hour. In addition to this valuable apparatus are two other seismometrographs (Brassart's and Cecchi's), a Guzzanti microseismoscope, one of Agamennone's photographically recording tromometers, a Cancani photochronograph, which, at the moment of a shock, photographs the face of a clock, four seismographic pendulums of different lengths and masses, ten seismoscopes of various patterns for calling attention to the occurrence of a shock, and a puteometer which records the movements of the water-surface in a well 32½ metres deep.

WE have received from the Meteorological Reporter for Western India a copy of his "Brief Sketch of the Meteorology of the Bombay Presidency for the Year 1896–97." The weather during the year presented several features of unusual character: for instance, unseasonable distribution of rainfall, for, although the annual amount was above the average in most districts, the deficiency was very great in September and October, and it was owing to this that the crops withered and caused widespread famine. Another feature was the prevalence of abnormally high temperatures; in April and October the means were respectively 6° and 7° above the average. These conditions appeared to have considerable effect upon the plague; from August to November the mortality increased with an abnormal rise of temperature, and *vice versâ*, whereas the high temperature of April appears to have had the effect of decreasing the mortality in that month. This report contains some interesting details of floods in the river Tapti since 1727; the highest flood on record—viz. 100½ feet—occurred in July 1883, while that of July 1896—viz. 98 feet—occupies the third place on record.

THE part for January 1898 of "The Garden," edited by Mr. W. Robinson, presents a very attractive contents to the gardener and horticulturist. There are longer or shorter notes on almost every department of gardening; and no less than four coloured plates, besides numerous woodcuts, are included in the price of one shilling.

In the *Journal* of the Royal Society of Bengal for 1897 (part ii. No. 2) is a brief article by Mr. F. Finn, of the Indian Museum, on the Theory of Warning Colours and of Mimicry. [illegible] a series of experiments on a tree-shrew, *Tupaia ferruginea*, and on a bull-frog, *Rana tigrina*, but the results do not appear to be very conclusive.

DR. L. MESCHINELLI, of Vicenza, has issued a prospectus of a proposed Iconograph of all Fossil Fungi at present known. It will be published, probably in the earlier half of the present year, in the form of a quarto volume, with an atlas of more than thirty plates. The price to subscribers will be 30 francs, delivered free.

IN a paper in *Natural Science* for August 1897, Mr. G. W. Bulman adopts very much the view of Prof. Plateau, that bees are not primarily attracted to flowers by their conspicuous colour, especially that they have no special partiality for blue. He also contests the statement that either honey-bees or wild bees are constant in their visits to the same species. Somewhat similar results appear to have been arrived at by Mr. Albert Gale from observations in Australia, of the record of which we find a commencement in the *Agricultural Gazette of New South Wales* for November 1897.

IN our recent review of the "Vita Medica" of the late Sir B. W. Richardson, the author's part in emphasising the distinction between "enteric and typhoid (*sic*) fevers" was alluded to (p. 265). Our readers perceived at once, no doubt, that the name "typhoid" had crept into the text in place of typhus.

UNDER the title of *The Home University*, the publication of a magazine and note-book for private students of various branches of knowledge has just been commenced. The idea of the editors of the new periodical is to give the home-student assistance on difficult points, and furnish him with aids to memory. "We shall assume," it is added, "that, in addition to a knowledge of their own language, our readers possess the rudiments of French, Latin, German, and Greek, and that respecting Geography, History, Poetry, and the Natural Sciences they have made some kind of a beginning." The editors purpose not so much to try to increase knowledge as to convey it, and we wish them success in their undertaking, notwithstanding the fact that science takes a minor place in the first number of their educational medium. The periodical is published by the Educational Museum, Haslemere, and by Messrs. West, Newman, and Co.

THE additions to the Zoological Society's Gardens during the past week include a Red Fox (*Canis fulvus*) from North America, presented by Mr. F. C. Ingram; four Virginian Opossums (*Didelphys virginiana*) from North America, presented by Mr. J. D. Sprunt; two Secretary Vultures (*Serpentarius reptilivorus*) from South Africa, presented by Mr. J. E. Matcham; a Laughing Kingfisher (*Dacelo gigantea*), a Lace Monitor (*Varanus varius*), a Blue-tongued Lizard (*Tiliqua scincoides*), two Stump-tailed Lizards (*Trachydosurus rugosus*) from Australia, presented by Mr. J. D. Waley; a Leopard (*Felis pardus*) from Ceylon, a Derbian Wallaby (*Macropus derbianus*) from Australia, deposited; two Uvæan Parrakeets (*Nymphicus uvæensis*) from the island of Uvea, Loyalty Group; two Black-headed Caiques (*Caica melanocephala*) from Demerara, an Ashy-black Ape (*Macacus ocreatus*) from the East Indies, three Curlews (*Numenius arquata*), three Oyster-catchers (*Hæmatopus ostralegus*) from Holland, purchased.

OUR ASTRONOMICAL COLUMN.

THE SOLAR ECLIPSE.—Mr. F. W. Dyson, the Chief Assistant at the Greenwich Observatory, has sent the following letter to the press:—"Prof. Turner telegraphs from Bombay that the observations of the solar eclipse were very successful. The photographs taken by the Astronomer Royal, Prof. Turner, Captain Hills, Mr. Newall, and Dr. Copeland, have all been developed, and the results are excellent. Captain Hills has succeeded in photographing the spectrum of the reversing layer, and Prof. Turner has obtained marked results as to the amount of polarisation of the corona."

LARGE AND SMALL PROPER MOTIONS.—In the *Astronomische Nachrichten* (No. 3466) Prof. Kapteyn announces the discovery of a star with an exceedingly large proper motion; this is the star in the Cordoba Zone Catalogue 5·243h., of about the 8th magnitude, but probably slightly variable, and having an orange-yellow colour. Its position from the "Cape" observations of 1897·8 for epoch 1875 is α = 5h. 6m. 56·0s., and $\delta = -44^\circ\ 60'\cdot530$, which position is in the constellation of Pictor. The result of the investigations of Mr. Innes, of the Cape Observatory, and Prof. Kapteyn, gives the proper motion in a great circle as 8″·7, or in R.A., + 0·621s., and Decl. − 5″·70, which will be seen is even greater than that of the "runaway" star 1830 Groombridge, the proper motion of which, it will be remembered, is 7″·05 in a great circle, or in R.A. + 0·346s., and Decl. − 5″·78. We shall await with interest the determination of the parallax of this remarkable star, in order to discriminate whether its large proper motion is real or chiefly due to its close proximity to our system.

In contrast with the above, Mr. J. G. Porter has re-computed the proper motion of the star Bradley 2444^a = 3250, availing himself of a much longer series of observations than those from which Dr. Auwers deduced the values +0·0040s. and +0″·128; and while Mr. Porter's result of + 0·0024s. and − 0″·030 (as given in the *Astronomical Journal*, No. 422) confirms the small motion in right ascension, it negatives entirely the motion in declination; he therefore suggests that Dr. Auwers' result seems to have been due to a wrong reduction of the declinations of D'Agelet and Lalande.

THE COMET OF 1892 II.—It is not often that an opportunity occurs of basing the determination of a comet orbit on observations extending over so long a period as that available in the present instance. The series commenced in 1892, March 19, and ended 1893, January 12, during which period the comet passed over about 107° of true anomaly. The definitive orbit in this case proves to be hyperbolic, and the final result is entitled to considerable weight. The only unsatisfactory feature about it is the amount of the residuals in some of the normal places. Dr. L. Steiner, of O'Gyalla, who has made the calculations, bases them on Dr. Schorr's elements, from which he derives by comparison with his computed ephemeris, twelve normal places, necessarily varying considerably in point of accuracy. The solution of the equations of condition founded on these normal places gives for the excentricity the value 1·004404. The residuals to which we have referred as not being quite satisfactory do not occur at the end of the series, when the comet would necessarily be faintest and the observations scarcest, but in the middle of the series, practically from June to October. This is to some extent perhaps to be explained by the fact, that the comet was about that time very faint in telescopes of moderate size, and these observations, made with difficulty, may have had an injurious effect on those derived from the use of larger instruments. This explanation is not entirely satisfactory, for in one instance the normal place rests entirely on the measures made at one Observatory, that of Bordeaux. Dr. Steiner tries by alterations of the assigned "weights" to reduce these residuals, but the result is not quite satisfactory. Under the best circumstances, and when the excentricity is brought down to 1·000345, the sum of the squares of the residuals in the hyperbola is 103″·2, while on the assumption of parabolic motion the same sum is 279″·5. The orbit is almost perpendicular to the plane of the ecliptic.

WINNECKE'S COMET = *a* 1898.—From further observations made by Prof. Perrine at the Lick Observatory a new ephemeris of this comet has been determined; this, together with the elements, are given in the *Astronomical Journal* (No. 424) as follows:—

Elements.

T = 1898 March 20·392 G.M.T.

$$\left.\begin{array}{rrrr} & {}^\circ & ' & '' \\ \omega = & 173 & 21 & 10\cdot0 \\ \Omega = & 100 & 51 & 45\cdot5 \\ i = & 16 & 59 & 34\cdot0 \end{array}\right\} 1898\cdot0$$

$$\log e = 9\cdot854161$$
$$\log a = 0\cdot510521$$

Ephemeris for Greenwich Midnight.

1898.		App. α h. m. s.		App. δ ° ′ ″		log Δ
Feb. 1·5	...	17 25 1·63	...	−10 53 56·4		
3·5	...	34 33·95	...	11 17 21·0	...	0·1527
5·5	...	44 14·66	...	11 39 50·2		
7·5	...	17 54 3·34	...	−12 1 18·5	...	0·1457

The nearest bright star to the comet during this period is ο Serpentis, which rises about four hours in advance of the sun.

ROWLAND'S TABLES.—In the December number of the *Astrophysical Journal*, tables of *corrections* and *additions* to Prof. H. A. Rowland's table of solar spectrum wave-lengths are given. The errors in wave-length have been carefully determined for the whole table, but the identification of solar lines with the lines of the elements in the spectrum of the electric arc has been revised only from wave-length 3722 to 4175. Therefore the corrections and additions to the identifications have been given only for the most important lines between these limits. A few small solar lines have been added to the table.

The changes in wave-length are few, most of them being additions to the identifications.

NEBULÆ NEAR CASTOR.—Prof. Barnard records in the *Astronomical Journal* (No. 422) a list of new nebulæ which he found with the 12-inch equatorial when he first went to Mount Hamilton, and which have remained unpublished until now. There are five within less than a degree of Castor, whose positions here given are reduced to 1860·0—the epoch of Dreyer's New General Catalogue.

No.		α h. m. s.		δ ° ′		Description.
1	...	7 24 23	...	+31 44·4	...	Close p. 10 mag. star.
2	...	7 24 43	...	+31 35·5	...	Small, faint.
3	...	7 25 12	...	+31 40·5	...	Small, 3 S *s in curve 2′ p. ±
4	...	7 25 27	...	+31 40·5	...	Very, very faint.
5	...	7 25 59	...	+31 31·0	...	Small, faint.

Prof. Barnard remarks that he has discovered several nests of these nebulæ, but in most other cases the individual nebulæ are very much smaller.

DR. KARL NECKER.—The name of yet another astronomer has to be added to the death roll of last year. Dr. Karl Necker, who occupied the position of assistant in various observatories, was unfortunately killed in a railway accident at Cairo, to which town he had removed for the benefit of his health. Born in 1867, and with his University career only completed in 1893, he entered first the Strassburg Observatory as a temporary assistant, but after a few months removed to Vienna, and in the Kuffner Observatory devoted himself to making a series of observations on the prime vertical. When Dr. Halm left Strassburg to occupy his present position at Edinburgh, Dr. Necker returned to fill the vacancy thus created, and was engaged in the fundamental meridian work. But his health compelled him to take long rests, and finally he was recommended to reside in Cairo, where he hoped to secure a position in the Khedival Observatory. This hope was defeated by his tragic death, while making a short excursion to the Sinai Peninsula.

INSTINCT AND INTELLIGENCE IN ANIMALS.[1]

BIOLOGY is a science not only of the dead but of the living. The behaviour of animals, not less than their form and structure, demands our careful study. Both are dependent on that heredity which is a distinguishing characteristic of the organic world. And in each case heredity has a double part to play. It provides much that is relatively fixed and stereotyped; but it provides also a certain amount of plasticity or ability to conform to the modifying conditions of the environment. Instinctive behaviour belongs to the former category; intelligent behaviour to the latter. When a caterpillar spins its silken cocoon, unaided, untaught, and without the guidance of previous experience; or when a newly-mated bird builds her nest and undertakes the patient labours of incubation before experience can have begotten anticipations of the coming brood; we say that the behaviour is instinctive. But when an animal learns the lessons of life, and modifies its procedure in accordance with the results of its individual experience, we no longer use the term instinctive, but intelligent. Instinct, therefore, comprises those phases of active life which exhibit such hereditary definiteness as fits the several members of a species to meet certain oft-recurring or vitally-important needs. To intelligence belong those more varied modes of procedure which an animal adopts in adaptation to the peculiar circumstances of its individual existence. Instinctive acts take their place in the class of what are now generally known as congenital characters; intelligent acts in the class of acquired characters.

But the study of instinct and intelligence in animals opens up problems in a different field of scientific investigation. They fall within the sphere not only of biological but also of psychological inquiry. And in any adequate treatment of their nature and origin we must endeavour to combine the results reached by different methods of research in one harmonious doctrine. This involves difficulties both practical and theoretical. For those invertebrates, such as the insects, which to the naturalist present such admirable examples of instinctive behaviour, are animals concerning whose mental processes the cautious psychologist is least disposed to express a definite opinion. While the higher mammalia, with whose psychology we can deal with greater confidence, exhibit less typical instincts, are more subject to the disturbing influence of imitation, and, from the greater complexity of their behaviour, present increased difficulties to the investigator who desires carefully to distinguish what is congenital from what is acquired.

Nor do the difficulties end here. For the term "instinct" is commonly, and not without reason, employed by psychologists with a somewhat different significance, and in a wider sense than is necessary or even desirable in biology. The naturalist is concerned only with those types of behaviour which lie open to his study by the methods of direct observation. He distinguishes the racial adaptation which is due to congenital definiteness, from that individual accommodation to circumstances, which is an acquired character. But for the psychologist instinct and intelligence comprise also the antecedent conditions in and through which these two types of animal activity arise. The one type includes the conscious impulse which in part determines an instinctive response; the other includes the choice and control which characterise an intelligent act. When a spider spins its silken web, or a stickleback builds the nest in which his mate may lay her eggs, the naturalist describes the process and seeks its origin in the history of the race; but the psychologist inquires also by what impulse the individual is prompted to the performance. And when racial and instinctive behaviour is modified in accordance with the demands of special circumstances, the naturalist observes the change and discusses whether such modifications are hereditary; but the psychologist inquires also the conditions under which experience guides the modification along specially adaptive lines. Each has his part to play in the complete interpretation of the facts. And each should consent to such definitions as may lead to an interpretation which is harmonious in its results.

In view, therefore, of the special difficulties attendant on a combined biological and psychological treatment of the problems of animal behaviour, I have devoted my attention especially to some members of the group of birds in the early days of their life. And I shall therefore draw my examples of instinct and intelligence almost entirely from this class of animals. The organisation and the sensory endowments of birds are not so divergent from those of man, with whose psychology alone we are adequately conversant, as to render cautious conclusions as to their mental states altogether untrustworthy; when hatched in an incubator they are removed from that parental influence which makes the study of the behaviour of mammals more difficult; while the highly developed condition in which many of them first see the light of day affords opportunity for observing congenital modes of procedure under more favourable circumstances than are presented by any other vertebrate animals. Even with these specially selected subjects for investigation, however, it is only by a sympathetic study and a careful analysis of their behaviour that what is congenital can be distinguished from what is acquired. For from the early hours of their free and active life, the influence of the lessons taught by experience makes itself felt. Their actions are the joint product of instinct and intelligence, the congenital modes of behaviour being liable to continual modification in adaptation to special circumstances.

---

[1] A Friday evening discourse delivered at the Royal Institution, on January 28, by Prof. C. Lloyd Morgan.

Instinct appears to furnish a ground-plan of procedure which is shaped by intelligence to the needs of individual life. And it is often hard to distinguish the original instinctive plan from the subsequent intelligent modification.

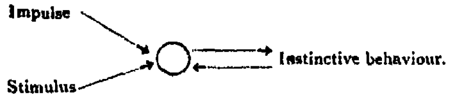
It is not my purpose to describe here in detail, as I have done elsewhere, the results of these observations. It will suffice to indicate some of the more salient facts. In the matter of feeding, the callow young of such birds as the jackdaw, jay, or thrush, instinctively open wide their beaks for the food to be thrust into their mouths. Before the eyes have opened the external stimulus to the act of gaping would seem to be either a sound or the shaking of the nest when the parent bird perches upon it. Under experimental conditions, in the absence of parents, almost any sound, such as a low whistle, lip-sound, or click of the tongue, will set the hungry nestlings agape, as will also any shaking or tapping of the box which forms their artificial nest. And no matter what is placed in the mouth the reflex acts of swallowing are initiated. But even in these remarkably organic responses the influence of experience soon makes itself felt. For if the material given is wrong in kind or distasteful, the effect is that the bird ceases to gape as before to the stimulus. Nor does it continue to open the beak when appropriate food has been given to the point of satisfaction. These facts show that the instinctive act is prompted by an impulse of internal origin, hunger, supplemented by a stimulus of external origin, at first auditory but later on, when the eyes are opened, visual. They show also that when the internal promptings of hunger cease, owing to satisfaction, the sensory stimulus by itself is no longer operative. And they show, too, that the diverse acts of gaping and swallowing become so far connected, that the experience of distasteful morsels tends, for a while at least, to prevent further gaping to the usual stimulus.

With those birds which are active and alert soon after hatching, the instinctive acts concerned in feeding are of a different character. At first, indeed, the chick does not peck at grains which are placed before it; and this is probably due to the fact that the promptings of hunger do not yet make themselves felt, there being still a considerable supply of unabsorbed yolk. Soon, however, the little bird pecks with much, but not quite perfect, accuracy at small near objects. But here again experience rapidly plays its part. For if distasteful objects, such as bits of orange-peel, are the first materials given, pecking at them soon ceases; and if this be repeated, the little bird cannot again be induced to peck, and may even die of starvation. This makes it very difficult to rear by hand some birds, such as plovers, whose natural food, in due variety, is not readily obtainable. It must be remembered, too, that under natural conditions the parent bird calls the young and indicates with her beak the appropriate food; and this appears to afford an additional stimulus to the act of pecking. Pheasants and partridges seem to be more dependent on this parental guidance than domestic chicks, and they are more easily reared when they have somewhat older birds as models whose pecking they may imitate. Passing allusion may here be made to a type of instinctive response in some respects intermediate between the upward gaping of the jay and the downward pecking of the chick. It is seen in the young moorhen, which pecks upwards at food held above it and cannot at first be induced to take any notice of food on the ground. Under natural conditions it is fed by the parent, which holds the food above the little bird as it floats on the water.

We have then, in these simple instinctive acts, examples of behaviour which is congenitally definite in type for each particular species; of actions which are the joint product of an internal factor, hunger, and an external factor, sensory impressions; of complex modes of procedure which subserve certain vital needs of the organism. It should be mentioned, however, that the relative definiteness of instinctive responses has been subjected to criticism from a psychological source. It has been urged that the nutritive instincts, the play instincts, the parental instincts, those of self-preservation and those concerned in reproduction, are so varied and multifarious, that definiteness is the last thing that can be predicated of them. Varied and multifarious they are indeed; and each of the groups above mentioned contains many differing examples. But that is because we are dealing with comprehensive classes of instinctive behaviour. The fact that the group of fishes includes organisms of such wide structural diversity, as the salmon, the globe-fish, the eel, and the sole, does not affect the fact that these species have a relatively definite structure each after his kind. It is only when we treat a group of fishes as if it were an individual fish that we are troubled by indefiniteness of structure. And it is only when we deal with a group of instincts, comprised under a class-name, as if it were a particular instinctive act, that we fail to find that definiteness which, to the naturalist, is so remarkable.

From the physiological point of view, instinctive procedure would seem to have its origin in an orderly group of outgoing neural discharges from the central office of the nervous system giving rise to a definite set of muscular contractions. And this appears to have an organic basis in a congenital preformation in the nervous centres, the activity of which is called into play by incoming messages, both from internal organs in a state of physiological need, and from the external world through the organs of special sense. The naturalist fixes his attention chiefly on the visible behaviour which is for him the essential feature of the instinctive act. But in view of the requirements of psychological interpretation it is advisable to comprise under the term instinct, in any particular manifestation of its existence, the net result of four things: first, internal messages giving rise to the impulse; secondly, the external stimuli which co-operate with the impulse to affect the nervous centres; thirdly, the active response due to the coordinated outgoing discharges; and fourthly, the message from the organs concerned in the behaviour by which the central nervous system is further affected. Now I shall here assume, without pausing to adduce the arguments in favour of this view, that consciousness is stirred in the brain, only by incoming messages. If this be so, the outgoing discharges which produce the behaviour are themselves unconscious. Their function is to call forth adaptive movements; and these movements give rise to messages which, so to speak, afford to consciousness information that the instinctive act is in progress. Hence I have urged that the instinctive *performance* is an organic and unconscious matter of the purely physiological order, though its effects are quickly communicated to consciousness in the form of definite messages from the motor organs. I have not denied that the stimuli of sight, touch, hearing and so forth, also have conscious effects; I do not deny (though here I may have spoken too guardedly) that the initiating impulse of internal origin, is conscious. In both these cases we have messages transmitted to the central office of the brain. What I have ventured to urge is that the consciousness of instinctive behaviour, *in its completed form*, does not arise until further messages come in from the motor organs implicated in the performance of the act, lodging information at the central office concerning the nature of the movements.

A diagram will perhaps serve to make this conception clearer.



The circle represents the brain, in some part of which consciousness arises through the effects of incoming nerve-currents. Under the influence of the two primary groups of messages, due to impulse and to sensory stimulus, consciousness is evoked, and the brain is thrown into a state of neural strain, which is relieved by the outgoing discharge to the organs concerned in the instinctive behaviour. It is this outgoing discharge which I regard as unconscious. But the actions which are thus produced give rise to a secondary group of incoming messages from the moving limbs. This it is which gives origin to the consciousness of instinctive behaviour as such. And I regard it as psychologically important that these incoming messages are already grouped, so as to afford to consciousness information, rather of the net results of movement than of their subsidiary details.

So much for our general scheme. If now we turn to the instinctive behaviour concerned in locomotion, we find a congenital basis upon which the perfected activities are founded. There is no elaborate process of learning to walk on the part of the chick; ducklings and moorhens a few hours old swim with perfect ease when they are placed in water; these birds also dive without previous practice or preliminary abortive attempts; while young swallows, if their wings are sufficiently large and strong, are capable of short and guided flights the first time they are committed to the air. In these cases neither the internal impulse, nor the sensory stimuli, are so well defined as in the case of the nutritive activities. The impulse probably takes the form of an uneasy tendency to be up and doing, perhaps due to ill-defined nervous thrills from the organs of locomotion which are in need of exercise. The sensory stimuli are presumably afforded by the contact of the feet with the ground, or with the water, and by the pressure of the air on the wing-surfaces. It is a curious fact that, if young ducklings be placed on a cold and slippery surface, such as that of a japanned tea-tray, they execute rapid scrambling movements, suggestive of attempts to swim, which I have never seen in chicks, pheasants, or other land-birds.

It will not be supposed that I claim for perfected locomotion, so admirably exemplified in the graceful and powerful flight of birds, an origin that is wholly instinctive and unmodified by the teachings of experience. Here as elsewhere instinct seems to form the ground-plan of activities which intelligence moulds to finer and more delicate issues. This is the congenital basis on which is built the perfected superstructure. And if our opportunities for observation, and our methods of analysis, were equal to the task, we should be able to distinguish, in the development of behaviour, the congenital outline from the shading and detail which are gradually filled in by the pencil of experience.

The difficulties which render this analysis at the best imperfect are, therefore, twofold. In the first place, intelligence begins almost at once to exercise its modifying influence; and in the second place, many instinctive traits do not appear until long after intelligence has begun its work. Much of the intelligent detail of the living picture is filled in before the instinctive outlines are complete. The term "deferred instincts" has been applied to those congenital modes of procedure which are relatively late in development. The chick does not begin to scratch the ground, in the manner characteristic of rasorial birds, till it is four or five days old; nor does it perform the operation of sand-washing till some days later; the moorhen does not begin to flick its tail till it is about four weeks old; the jay does not perform the complex evolutions of the bath till it has left the nest and felt its legs, when the stimulus of water to the feet, and then the breast, seems to start a train of acts which, taken as a whole, are of a remarkably definite type. The development of the reproductive organs brings with it, apart from the act of pairing, a number of associated modes of behaviour—nest-building, incubation, song, dance, display, and strange aerial evolutions—which are presumably in large degree instinctive, though of this we need more definite evidence. For it is difficult to estimate with any approach to accuracy the influence of imitation. There seems to be no reason for doubting that, when an animal grows up in the society of its kind, it is affected by what we may term the traditions of its species, and falls into the ways of its fellows, its imitative tendency being subtly influenced by their daily doings. The social animal bears the impress of the conditions of its peculiar nurture. Its behaviour is in some degree plastic, and imitation helps it to conform to the social mould.

The exact range and nature of the instinctive outline, independently of those modifications of plan which are due to the inherent plasticity of the organism, are, therefore, hard to determine. And if, as we have good grounds for believing, the growth of intelligent plasticity, in any given race, is associated with a disintegration of the instinctive plan, congenital adaptation being superseded by an accommodation of a more individualistic type, to meet the needs of a more varied and complex environment, the problems with which we have to deal assume an intricacy which at present defies our most subtle analysis.

We must now turn to the consideration of the manner in which individual accommodation through the exercise of intelligence under the teachings of experience, is brought about. And it will be well to pave the way by adducing certain facts of observation.

Although the pecking of a young chick under the joint influence of hunger and the sight of a small near object, would seem to belong to the instinctive type, the selection of appropriate food, apart from the natural guidance of the hen, seems to be mainly determined by individual experience. There is no evidence that the little bird comes into the world with anything like hereditary knowledge of good and evil in things eatable. Distasteful objects are seized with not less readiness than natural food such as grain, seeds, and grubs. The conspicuous colours of certain nasty caterpillars do not appeal to any inherited power of immediate discrimination so as to save the bird from bitter experience. They seem rather to serve the purpose of rendering future avoidance, in the light of this bitter experience, more ready, rapid, and certain. Bees and wasps are seized with neither more nor less signs of fear than large flies or palatable insects. Nor does there seem to be any evidence of the hereditary recognition of natural enemies as objects of dread. Pheasants and partridges showed no sign of alarm when my dog quietly entered the room in which they were kept. When allowed to come to closer quarters, they impudently pecked at his claws. A two days chick tried to nestle down under him. Other chicks took no notice of a cat, exhibiting a complete indifference which was not reciprocated. A moorhen several weeks old would not suffer my fox-terrier to come near his own breakfast of sopped biscuit, but drove him away with angry pecks until the higher powers supervened.

It is not, of course, to be inferred from these observations that such an emotion as fear has no place in the hereditary scheme, or that the associated acts of hiding, crouching, or efforts to escape do not belong to the instinctive type. I have seen little pheasants struck motionless, plovers crouch, and moorhens scatter at the sound of a loud chord on the violin, or of a shrill whistle. A white stoneware jug, placed in their run, caused hours of uneasiness to a group of birds, including several species. But there is no evidence that, in such cases, anything like hereditary experience defines those objects which shall excite the emotion. It is the unusual and unfamiliar object, especially after some days of active life amid surroundings to which they have grown accustomed; it is the sudden sound, such as a sneeze, or rapid movement, as when a ball of paper is rolled towards them, that evokes the emotion. Hence, if the parent birds are absent, the stealthy approach of a cat causes no terror in the breasts of inexperienced fledglings. But when she leaps, and perhaps seizes one for her prey, the rest scatter in alarm, and for them the sight of a cat has in the future a new meaning.

The elementary emotions of fear, anger, and so forth, stand in a peculiar and special relationship to instinct. At first sight they seem to take rank with the internal impulses which are the part-determinants of instinctive behaviour. The crouching of a frightened plover or landrail, the dive of a scared moorhen, result partly from the external stimulus afforded by the terrifying object, partly from the emotional state which that object calls forth. But in their primary genesis I am disposed—here following to some length the lead of Prof. Wm. James—to assign to such emotions an origin similar to that of the consciousness which follows on the execution of the instinctive act. Assuming, as before, that consciousness owes its genesis to messages which reach the sensorium through incoming nerve-channels, the sensory stimuli, afforded, let us say, by the sight of a terrifying object, do not seem, in the absence of inherited experience, capable of supplying messages which in themselves are sufficient to generate the emotion of fear. Now, the well-known accompaniments of such an emotional state are disturbances of the heart-beat, the respiratory rhythm, the digestive processes, the action of the glands, and the tone of the minute blood-vessels throughout the body. And all these effects are unquestionably *produced* by outgoing discharges from the central nervous system. But they are *felt* as the result of incoming messages, like vague and disquieting rumours, transmitted to the central office from the fluttering heart, the irregular breathing, the sinking stomach, and the disturbed circulation. Is it not therefore reasonable to suppose that the emotion, in its primary genesis, is due to the effect on the sensorium of these disquieting messages? If this be admitted as a working hypothesis—and it cannot at present claim to be more than this—we reach, at any rate, a consistent scheme. As primary messages to the central office of consciousness we have, on the one hand, those due to stimuli of the special senses, and, on the other hand, those resulting from the conditions of the bodily organs, taking the form of a felt craving for their appropriate exercise. These cooperate to throw the brain into a state of unstable equilibrium or neural strain, which is relieved by outgoing streams of nervous energy. And these in turn fall into two groups; first, an orderly set of discharges to the voluntary muscles concerned in behaviour, and secondly, a more diffuse group of discharges to the heart, respiratory apparatus, digestive organs, glands, and vascular network. In so far as these are outgoing discharges, they do not directly affect consciousness. But there quickly returns upon the sensorium an orderly group of incoming messages from the motor apparatus concerned in instinctive behaviour, and a more indefinite group from the heart and other visceral organs. The former gives the well-defined consciousness of activity; the latter the relatively ill defined feelings which are classed as emotional. But so swift is the backstroke from the body to the brain that, ere the instinctive behaviour is complete, messages from the limbs—and, under the appropriate circumstances, from the heart—that is to say, of both instinctive and emotional origin—begin to be operative in consciousness, and the final stages of a given performance may be guided in the light of the experience gained during its earlier stages.

The exact manner in which consciousness exercises its guiding influence, is a matter of speculation. Perhaps the most probable hypothesis is that the cerebral hemispheres are an adjunct to the rest of the central nervous system, and exercise thereon by some such mechanism as the pyramidal tract in the human subject, a controlling influence. Given an hereditary ground-plan of automatic and instinctive responses the cerebral hemispheres may, by checking here and enforcing there, limit or extend the behaviour in definite ways. In any case, from the psychological point of view, their action is dependent on three fundamental properties: first, the retention of modifications of their structure; secondly, differential results according as these modifications have pleasurable or painful accompaniments in consciousness; and thirdly, the building of the conscious data, through association, into a system of experience. The controlling influence of this experience is the essential feature of active intelligence. Or, expressed in the almost obsolete terminology of the older psychology, intelligence is the faculty through which past experience is brought to bear on present behaviour.

Prof. Stout, whose careful work in analytical psychology is well known, has done me the service of criticising, in a private communication, my use of the phrase "past experience," urging that present experience is not less important in determining behaviour than that which is past and which can only be operative through its revival in memory. The criticism is valid in so far as it shows that I have not been sufficiently careful to define what I mean by past experience. But I certainly had in mind, though I did not clearly indicate, the inclusion of what Mr. Stout regards as present experience. My conception of "present," as I have elsewhere described it, is that short but appreciable period of time, occupying only some small fraction of a second, which is comprised in the fleeting moment of consciousness. All anterior to this, if it were but a second ago, I regard as past—past, that is to say, in origin, though still operative in the limited field of the present moment. When we are reading a paragraph and near its close, the net result of all that we have read in the earlier sentences, is present to influence the course of our thought. But the very words—"all that we *have* read"—by which we describe this familiar fact, imply that the guiding experience originated in a manner which demands the use of the past tense. Still I am none the less grateful to Mr. Stout for indicating what to many may have seemed a serious omission in my interpretation. Suffice it to say that if we include under the phrase "present experience" the occurrences of five minutes, or even of five seconds ago (all of which I regard as past), I most fully agree that present experience (in this sense) exercises a most important guiding influence.

We have distinguished four classes of messages affecting consciousness in the central office of the sensorium: first, stimuli of the special senses; secondly, internal cravings; thirdly, motor sensations due to bodily activity; and fourthly, emotional states. These are combined in subtle synthesis during the growth of experience, and are associated together in varied ways. Into the manner in which experience grows we cannot enter here. It will be sufficient to indicate very briefly the effects of this growth on the behaviour of animals in the earlier stages of their life. This may be considered from a narrower or from a broader standpoint. In the narrower view we watch how, within the field of a widening synthesis, the particular associations are formed. We see how, within experience, the taste and appearance of certain caterpillars or grubs become so associated that for the future the larva is left untouched. Or we see how the terrible pounce of the cat has become so associated with her appearance as thenceforth to render her an object of fear to enlightened sparrows. But of the physiological mechanism of association we know little.

There is a familiar game in which a marble is rolled down an inclined board at the bottom of which are numbered compartments. The lower part of the board is beset with a series of vertical pins so arranged that the marble rebounding from one to another pursues a devious course before it reaches its destination. But if we tie threads from pin to pin we may thus direct the course of the marble along definite lines. Now the brain may be roughly likened to a set of such pins, and the marble to an incoming nerve current. The congenital structure is such that a number of hereditary threads connect the pins in definite ways, and direct the discharge into appropriate channels. But a vast number of other threads are acquired in the course of individual experience. These are the links of association which direct the marble in new ways. Observation of behaviour can only give us information that new directing threads have been introduced. The psychology of association can only indicate which pins have been connected by linking threads. Even such researches as those of Flechsig can at present do no more than supplement the psychological conclusion by general anatomical evidence. Of the details of brain modification by the formation of association fibres we are still profoundly ignorant.

Nor when we turn from the narrower to the wider point of view are we in better case. We are forced to content ourselves with those generalities which are the makeshift of imperfect knowledge. Still, even such generalities are of use in showing the direction in which more exact information is to be sought. And we can, perhaps, best express the net result of acquired modification of brain-structure by saying that every item of experience makes the animal a new being with new reactive tendencies. The sparrows, which yesterday were unaffected by the stealthy approach of the cat, garrulously scatter to-day because they are not the same simple-minded sparrows that they were. The chick comes into the world possessed of certain instinctive tendencies—with certain hereditary directing threads. But at the touch of experience its needs are modified or further defined. New connecting threads are woven in the brain. On the congenital basis has been built an acquired disposition. The chick is other than it was, and reacts to old stimuli with new modes of behaviour.

In its early days the developing animal is reading the paragraph of life. Every sentence mastered is built into the tissue of experience, and leaves its impress on the plastic, yet retentive brain. By dint of repetition, the results of acquisition become more and more firmly ingrained. Habits are generated; and habit becomes second nature. The organism which to begin with was a creature of congenital impulse and reaction becomes more and more a creature of acquired habits. It is a new being, but one with needs not less imperious than those with which it was congenitally endowed.

All of this is trite and familiar enough. But it will serve its purpose if it help us to realise how large a share acquired characters take in the development of behaviour in the higher animals, and how fundamentally important is the plasticity of brain-tissue, and its retentiveness of the modifications which are impressed on its yielding substance.

Such being the relations of intelligence and instinct in the individual, what are their relations in the evolution of the race? Granting that instinctive responses are definite through heredity, how has this definiteness been brought about? Has it been through natural selection? Or are the acquired modifications of one generation transmitted through heredity to the next? Is instinct inherited habit? Darwin, who wrote before the transmission of acquired characters was seriously questioned, admitted both. And Romanes, to whose ever-kindly sympathy I am deeply indebted, still adhered to this view in spite of modern criticism. There is not much in my own observational work which has any decisive bearing on the question. But there are one or two points which are perhaps worthy of consideration. The part played by acquisition in the field of behaviour is the establishment of definite relations between particular groups of stimuli and adaptive responses. If this be so, and if acquired modifications of brain-structure be transmitted, we might reasonably expect that the sight of a dog would have a similar effect on young pheasants to that which it has on their parents. But this does not appear to be the case. Again, one might reasonably expect that the sight of water would evoke a drinking response in recently hatched birds, just as the sight or scent of a Yucca flower excites a definite response in the Yucca moth. But here, too, this is not so. Thirsty chicks and ducklings seem to be uninfluenced by the sight of water in a shallow tin. They may even run through the liquid and remain unaffected by its presence. But if they chance to peck at a grain at the bottom of the tin, or a bubble on the water, as soon as the beak touches the liquid, *this* stimulus at once evokes a drinking response again and again repeated. Why does the touch of water in the beak excite a congenital response, while the sight of water fails to do so? I believe it is because under natural conditions the chicks peck at the water in imitation of the mother, who thus shields them from the incidence of natural selection. Under these circumstances there is no opportunity for the elimination of those who fail to respond at the mere sight of water, and consequently no selective survival of those who do thus respond. But though the hen can lead her young to peck at the water, she cannot teach them the essential movements of beak, mouth, and gullet, which are necessary for the complex act of drinking. In this matter she cannot shield them from the incidence of natural selection. Those which, on pecking the water, failed to respond to the stimulus by drinking, would assuredly die of thirst and be eliminated. The rest would survive and transmit the congenital instinctive tendency. Thus it would seem that when natural selection is excluded a special mode of behaviour has not become congenitally linked with a visual stimulus; but, when natural selection is in operation, this behaviour has become so linked with a touch or taste stimulus in the beak. Similarly in the case of the pheasants and the dog. The parent birds warn the young of his approach, and thus prevent the incidence of natural selection. Hence there is no instinctive response to the sight of a terrier.

No doubt there are many cases of complex behaviour, seemingly instructive, which are difficult to explain by natural selection alone, and which have the appearance of being due to the inheritance of acquired habits. I have, however, elsewhere suggested that acquired modifications may, under the conditions of natural selection, foster the development of "coincident" variations of like nature and direction, but having their origin in the germinal substance. But into a consideration of this hypothesis I cannot here enter. Without assuming a dogmatic attitude, I am now disposed to regard the direct transmission of acquired modes of behaviour as not proven.

Thus we come back to the position, assumed at the outset, that heredity plays a double part It provides, through natural selection or otherwise, an outline sketch of relatively definite behaviour, racial in value; it provides also that necessarily-indefinite plasticity which enables an animal to acquire and to utilise experience, and thus to reach adaptation to the circumstances of its individual life. It becomes, therefore, a matter of practical inquiry to determine the proportion which the one kind of hereditary legacy bears to the other. Observation seems to show that those organisms in which the environing conditions bear the most uniform relations to a mode of life that is relatively constant, are the ones in which instinct preponderates over intelligent accommodation; while those in which we see the most varied interaction with complex circumstances, show more adaptation of the intelligent type. And the growth of individual plasticity of behaviour, in race-development, would seem to be accompanied by a disintegration of the definiteness of instinctive response, natural selection favouring rather the plastic animal capable of indefinitely varied accommodation than the more rigid type whose adaptations are congenitally defined.

I have dealt, it will be observed, only with the lower phases and earlier manifestations of intelligence. Its higher development, and the points in which it differs from the more complex modes of human procedure, offer a wide and difficult field for careful observation and cautious interpretation. I have recently attempted further investigations in this field; but they concern rather the relation of intelligence to logical thought than that of instinct to intelligence, which forms the subject of this discourse.

THE DUKE OF DEVONSHIRE ON TECHNICAL EDUCATION.

At Eastbourne on Saturday last the Duke of Devonshire addressed the students of the art and technical classes, and in the course of his remarks he referred to educational questions of more than local interest. His remarks upon proprietary and private schools call attention to what is probably the weakest link in our educational system. In order to qualify for an assistant mastership in an elementary school, it is necessary for a teacher to serve a term of years, during which period his knowledge of the theory and practice of teaching is periodically tested; but in our private and proprietary schools any one can be a teacher, whether he possesses qualifications or not. In other words, the elementary school teacher must prove his efficiency, while the teacher in the middle-class schools—the respectable proprietary establishments—may or may not be competent to impart instruction. The result is that some of our higher-grade primary schools are the best organised and equipped institutions for teaching elementary science in the country, while the science which figures in the prospectuses of many private schools is entirely unworthy of the name. Unfortunately, the sons of artisans and shopkeepers are compelled to leave school at an early age, and so cannot take full advantage of the facilities provided by the higher-grade schools. On the other hand we have the private schools where the age of leaving is later, but there the facilities for scientific instruction are inadequate. The general result is that only a small proportion, either of the artisan class or of the sons of commercial men, receive technical instruction. It is, of course, not suggested that all private schools are inefficient, but a large proportion of them are, when considered as schools in which science is taught; and the Duke of Devonshire has done a public service in pointing out the need of subjecting them to some system of supervision.

The following is abridged from the *Times* report of the Duke of Devonshire's address:—

Proprietary and Private Schools.

I suppose that there are in Eastbourne a larger number of proprietary and private schools than in almost any other town of the same size in the country. It would be extremely interesting to have full information as to what these schools are doing and the nature of the instruction which they provide. I doubt very much whether there is any one here, or whether there is anybody anywhere, who has the means of forming or giving a complete account of what the proprietary and private schools of any particular district in the country are doing, or what is the nature of the instruction which they are providing. That appears to me to point to the need for some better organisation of education than we at present possess. Of the students who are receiving their education in the numerous proprietary schools here and in other similar schools in the country there are many, no doubt, whose future would not be dependent upon their own exertions, and who are only educating themselves, or being educated by their parents, to make them good citizens and cultivated people; but there must be a very large number in addition who are looking forward to entering into some profession or another, or into some branch of industry or of commerce. And to the parents of such students it would be of immense value and importance to have full knowledge and full information upon the character of the education which is being given at these proprietary and private schools. Some of them, no doubt, are more efficient; some are less efficient than others; but, even amongst those which are the most efficient, there must be some which are capable of giving a more valuable hint and direction of instruction to those who are going to enter upon industrial and commercial pursuits than those which may be in other directions equally efficiently organised; and it would be of the very greatest importance, in my opinion, to the schools themselves, to the parents, and to the community at large if means were at our disposal to know more of the manner in which these schools are organised and of the work which they are doing.

Technical Education Abroad.

Foreign nations have anticipated us to a very great extent in realising the close connection which exists between education and industrial and commercial success. That is a fact which is being brought home to us almost daily in various directions of the increasing competition to which we find ourselves in every quarter exposed. It is a subject which, as your chairman has reminded you, I have frequently discussed on previous occasions, and I am not going to enter into it at any length again to-night. I will only say that the urgency of this question is now recognised by those who are educational experts or educational enthusiasts. The urgency of the question is coming to be recognised by practical men of business. Only the other day the education authority of Manchester sent out a deputation of its members to ascertain what provision was being made in Germany and Switzerland for the industrial and commercial education of the people. They published a most valuable report, in which they spoke almost with dismay of the completeness with which the education of those who were leading and directing the manufacturing and commercial enterprise of those countries was being organised; and they urged upon their fellow-citizens, in the very strongest terms, that they should not allow themselves to be left behind in the race, but that they should make an effort for the organisation of the education of their own people to bring that education up to something like the level which has been attained in those countries. And the Associated Chambers of Commerce the other day presented a memorial, a most important memorial, to the Government urging upon them that greater attention should be paid by the educational departments of the State, not to art and scientific instruction only, but to the study of foreign languages and other subjects indispensable to the successful prosecution of a commercial career. And therefore I say it is not educational enthusiasts only, but it is practical and far-headed men of business who are beginning to realise the absolute necessity of bringing up our education somewhere near, at all events, to the levels which have been attained in other countries.

ORGANISATION OF SECONDARY EDUCATION.

I have not the smallest desire to see our secondary education modelled upon one uniform pattern. I believe that we require great variety and great freedom, but I do think that it would be of advantage if both central and local organisations existed with which these private institutions might place themselves in voluntary, but, at the same time, in close connection—organisations which, by means, perhaps, of inspection, by their guidance, and by their counsel—might enable them so to organise themselves, so to co-relate themselves, as to render the instruction which they may give more valuable to the public. These are, of course, observations of a very general character, which, if they have any substance, apply equally to schools in every part of the country. Speaking of this particular district—of your own schools—I cannot help thinking that it might be of great advantage, both to them and to the community of Eastbourne, if, under the county educational authority or under your borough educational authority—there ought not to be any jealousy between different bodies of that kind—there could be established in this town of Eastbourne a scientific and technical institute, which might be of great value to the inhabitants of Eastbourne itself and also of great assistance to those educational establishments which are so numerous amongst you, and which might make use of such establishments as part of their educational course.

PRIZE SUBJECTS OF THE PARIS ACADEMY OF SCIENCES.

THE *Comptes rendus* of the Paris Academy of Sciences, for January 10, contains the list of subjects proposed for the various prizes offered by the Academy for 1898 and three succeeding years.

For the year 1898, the subject for the Grand Prize of the Mathematical Sciences is to examine and extend the part played by divergent series in analysis; for the Bordin Prize (3000 fr.), to study the questions relating to the determination, properties, and applications of systems of orthogonal curvilinear coordinates of *n* variables, indicating especially the degree of generality of these systems; the Francœur Prize (1000 fr.) and Poncelet Prize (2000 fr.), for the most useful work in the field of pure or applied mathematics. In Mechanics, the Extraordinary Prize of 6000 fr., for progress in any direction calculated to increase the efficiency of the French naval forces; the Montyon Prize (700 fr.), for inventing or improving instruments useful to the progress of agriculture, the mechanical arts or sciences; the Plumey Prize (2500 fr.), for improvements in steam engines, or any other invention contributing to the progress of steam navigation; the Fourneyron Prize (500 fr.), for the theory of the motion of bicycles, discussing more especially the conditions of stability of both rectilinear and curved motion on a horizontal or inclined plane.

In Astronomy, the Lalande Prize (540 fr.), for the most interesting observation, or the work or memoir most useful to the progress of astronomy; the Damoiseau Prize (1500 fr.), for an exposition of the theory of the perturbations of Hyperion, the satellite of Saturn, taking account principally of the action of Titan, comparing the observations with the theory, and hence deducing the mass of Titan; the Valz Prize (460 fr.), for the most interesting astronomical observation made during the current year; the Janssen Prize (a gold medal), for discoveries in physical astronomy.

In Statistics, the Montyon Prize (500 fr.), for questions relating to French statistics; and in Chemistry, the Jecker Prize (10,000 fr.), for work in organic chemistry.

In Mineralogy and Geology, the Vaillant Prize (4000 fr.), for a work discussing and making known the indications furnished by the microscopical study of sedimentary rocks (particularly secondary and tertiary) from the point of view of their genesis and of the modifications which they have undergone since their deposit in structure and composition, organised bodies being included.

In Botany, the Barbier Prize (2000 fr.), for discoveries bearing upon the art of healing; the Desmazières Prize (1600 fr.), for the best study of Cryptogams; the Montagne Prizes (1000 fr. and 500 fr.), for memoirs bearing on the anatomy, physiology, and development of the lower Cryptogams; the De la Fons-Melicocq (900 fr.), for botanical work on the North of France; and the Thore Prize (200 fr.) to the author of the best work on the cellular Cryptogams of Europe.

In Anatomy and Zoology, the Savigny Prize (975 fr.), for the assistance of young travelling zoologists, not receiving Government support, who have specially occupied themselves with the invertebrate fauna of Egypt and Syria.

In Medicine and Surgery, a Montyon Prize for discoveries or inventions bearing on medicine or surgery; the Barbier Prize (2000 fr.), for the most valuable discovery in relation to the art of healing (surgery, medicine, pharmacy or botany); the Bréant Prize (100,000 fr.), for a discovery leading to the complete suppression of Asiatic cholera; the Godard Prize (1000 fr.), for the best memoir on the anatomy, physiology, and pathology of the genito-urinary organs; also the Bellion (1400 fr.); Mège Lallemand (1800 fr.), and Baron Larrey Prizes.

In Physiology, a Montyon Prize (750 fr.); the Pourat Prize (1400 fr.), for a memoir on the motor nerves of the stomach, and the Philipeaux Prize (890 fr.).

In Physical Geography, the Gay Prize (2500 fr.), for a comparison between the marine flora of the Bay of Biscay with that of neighbouring regions and of the Mediterranean; also to see if the fauna and flora lead to similar conclusions. Other general prizes offered are the Arago Medal, the Montyon Prize (unhealthy trades), the Trémont Prize (1100 fr.), the Gegner Prize (4000 fr.), the Delalande-Guérineau Prize (1000 fr.), the Jérome Ponti Prize (3500 fr.), the Leconte Prize (50,000 fr.), for a new and important discovery in mathematics, physics, chemistry, natural history, or medical science; the Tchiatcheff Prize (3000 fr.), for exploration of the lesser-known portions of Asia; the Houllevigue Prize, the Cahours Prize (3000 fr.), for the assistance of young chemists of promise; the Saintour Prize (3000 fr.), the Kastner-Boursault Prize (2000 fr.), for the best work on the applications of electricity in the arts, industry, and commerce; and the Estrade-Delcros Prize (8000 fr.).

Of these prizes, those of Montagne and Delalande-Guérineau are expressly restricted to Frenchmen, whilst the Lalande, La Caze, Delesse, Desmazières, Tchiatcheff, and Leconte Prizes are awarded without distinction of nationality.

MR. CAVENDISH ON HIS JOURNEY TO LAKE RUDOLF.

ON Monday last, Mr. H. S. H. Cavendish described his recent journey in East Africa before the Royal Geographical Society. Accompanied by Lieut. H. Andrew, Mr. Cavendish left Berbera on September 5, 1896, and proceeded in a southerly direction to Lugh, on the Juba River, afterwards striking westwards up the Dau. Here it proved very difficult to get into communication with the natives, as the caravan was at first taken for an Abyssinian force. The country of the Boran Gallas, with whom Dr. Donaldson Smith had so much trouble, was, however, soon reached. Mr. Cavendish gave some interesting details respecting this tribe, which he found most friendly, and anxious to be placed under British protection. Whilst in the Boran country the travellers were able to wander about at will without escort. At Egder, in about lat. 4° N., long. 39° E., Dr. Donaldson Smith's route was left, and the caravan made direct for Lake Stefanie, passing a remarkable crater with a lake at the bottom, from which salt is obtained. At the south end of Lake Stefanie a large outcrop of coal was discovered, which had evidently been laid bare by the action of the water. It was in this neighbourhood that Mr. Cavendish had an adventure with an elephant which well-nigh proved fatal. Some valuable information was collected with regard to the tribes on the western side of the lake, the principal of which are the Wanderobo (allied to the Borans), the Harbora, Hamerkoke (nomads), and Galubba. Striking across to the north end of Lake Rudolf, the travellers reached the country of the Reshiat or Darsonich, a race of traders, but, like other tribes of the country, almost entirely unclothed. A remarkable weapon in use among them is a kind of knife-bracelet, which is covered with a sheath, except during a fight.

The two Europeans now separated, Mr. Cavendish proceeding northwards to explore the river flowing into the north end of Lake Rudolf, whilst Lieut. Andrew marched down the east side of the lake. Like Captain Böttego, Mr. Cavendish is confident that the river, which he followed up for some distance, is identical with the Omo of travellers in the south of Abyssinia. The Legumi and Murle, who dwell on its banks, wear caps of human hair, into which ostrich feathers are stuck to denote the number of men killed by the wearer. The Murle also use the wrist-knife above described, as well as a kind of battle-axe with a wooden blade, covered with a tightly-stretched skin. Crossing the Omo, Mr. Cavendish proceeded southwards to the country of the Turkana on the west of Lake Rudolf, which had previously been entered by no travellers except the members of Böttego's expedition. Mount Lubur, an extinct volcano, was here ascended. The crossing of a sort of neutral zone at the border of the Turkana country is taken as a declaration of war, and the caravan was in consequence continually harassed by attacks from this warlike people. They are in the habit of making night attacks, and it was only by camping each night on spits of sand running out into the lake that these were successfully resisted. Finally friendly relations were established, and the Turkana guided the party through the difficult mountainous country towards the south. At the south end of Lake Rudolf Mr. Cavendish found that the Teleki volcano had entirely disappeared, the Ligob who dwelt in its neighbourhood telling him that, six months before, the lake had overflowed, and as the waters rushed towards the mountain there was a great explosion, since which a lava-plain has taken the place of the volcano, while a new crater has opened about three miles further south. The whole country seems to show signs of recent volcanic activity, for on the further march to the south, the caravan being once more united, a new lake was discovered containing a smouldering volcano, near which the water was quite hot to the touch. Where the water had dried up, the lake-bed was of black mud, hard on the surface, but hot and liquid below. Beyond this the country was exceedingly difficult, and water was scarce; but the caravan finally reached Lake Baringo, and thence made its way through known country to the east coast.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. E. W. Hobson, F.R.S., has been appointed a Governor of Derby School.

The original researches of Mr. J. A. McClelland, advanced student of Trinity College, have been approved by the Special Board for Physics and Chemistry as a qualification for the B.A. degree. Mr. McClelland's papers refer to work on the kathode, Lenard, and Röntgen rays.

Eighteen additional freshmen, including one advanced student, were matriculated on January 28.

MR. W. R. LANG has been appointed lecturer on organic chemistry at Glasgow University.

MR. PERCY A. HILLHOUSE has been appointed professor of naval architecture in the Imperial University, Tokio.

THE Cameron Prize of the University of Edinburgh, open each year to any one who in the preceding five years has made any "highly important and valuable additions to practical therapeutics," has (says the *British Medical Journal*) been awarded to Prof. T. R. Fraser, F.R.S., in recognition of his researches and practical therapeutic observations in connection with strophanthus.

THE fifth annual meeting of the Association of Technical Institutions was held on Friday last. Sir Bernhard Samuelson, Bart., who was elected president of the Association for the year 1898, delivered an address on the need of organised technical instruction. Resolutions were passed in favour of a system of examination and diplomas suitable more especially for day students who aspire to take leading positions in the various technical industries; and urging upon the Department of Science and Art the necessity of modifying the recent circular respecting the proportion of students who continue their studies in Schools of Science.

THE report of the Board of Agriculture on the distribution of the Parliamentary grant in aid of agricultural education in Great Britain during the year 1896–7 shows that sums amounting to a total of 6950*l.* were distributed in specific grants to fourteen institutions as follows:—Durham College of Science, Newcastle-on-Tyne, 1000*l.*; University College of North Wales, Bangor, 800*l.*; Yorkshire College, Leeds, 800*l.*; University College of Wales, Aberystwyth, 800*l.*; Reading University Extension College, 800*l.*; Nottingham University College, 600*l.*; Cambridge and Counties Agricultural Education Committee, 500*l.*; South-Eastern Agricultural College, Wye, 400*l.*; Eastern Counties Dairy Institute, Ipswich, 300*l.*; British Dairy Institute, Reading, 300*l.*; Bath and West and Southern Counties Society, 300*l.*; Royal Botanic Garden, Edinburgh, 150*l.*; Highland and Agricultural Society, 100*l.*; Agricultural Research Association, Aberdeen, 100*l.* The *Record of Technical and Secondary Education* states that in addition to the distribution of these sums, the Board have also undertaken the inspection of the agricultural work of the institutions and bodies assisted, as well as that of seven County Councils. A valuable feature of the report is the detailed information given regarding the agricultural instruction provided by the English and Welsh County Councils. From statistics compiled from this Return, it appears that a total sum of over 80,000*l.* (including a proportion of capital expenditure) was devoted during 1896–7 to agricultural instruction by sixty English and Welsh County Councils. Dairy instruction was taught in all but eight English and Welsh counties, and the manual processes of agriculture in about one-half the English counties.

AT the meeting of the London County Council on Tuesday, the Technical Education Board submitted an estimate of the amount that should be appropriated for technical education during the year 1898–99. The sum of 150,000*l.* was granted for the year 1896–97, and of this a balance of 13,384*l.* was unexpended. For the year ending March 31, 1899, it is estimated that 170,000*l.* will be required, in addition to this balance. The amount of the estimated expenditure is arrived at as follows:—For technical departments of polytechnics, 35,900*l.*; for various technical institutes, 36,000*l.*; for technical departments of public secondary day schools and allowance for fees, books, &c., of the Board's county scholars, 28,500*l.*; for higher education, 5500*l.*; for county scholarships, 31,025*l.*; for teaching in art, science, and technology and manual instruction, 27,800*l.*; for domestic economy, 7350*l.*; for commercial subjects, 3300*l.*; for museums (chiefly art examples), 1500*l.*; and for expenses of administration, 7300*l.* In a tabular statement the Board gives since the year 1890 the amount of the Exchequer contribution from beer and spirit duties, out of which the grant for technical education is made. From this it appears that the amount now asked for technical education, 170,000*l.*, will absorb almost the whole of the amount which the Council will receive from the beer and spirit duties, which is estimated for the ensuing year at 177,000*l.* The Council's grants towards technical education in London have gradually increased from the year 1892–93, when the grant was only 29,000*l.*, up to the present year, when the grant was 150,000*l.* For the ensuing year an additional 20,000*l.* is asked for.

ON Thursday last, at Grocers' Hall, the Speaker distributed the awards gained by students attending the technical colleges and schools which have been established by the City and Guilds of London Institute, under the direct management of its executive committee and maintained out of the funds of the institute contributed by the Corporation and Livery companies of the City of London. In the course of an address to the company, the speaker expressed surprise that more Englishmen did not come forward to fill in their own country posts in which a knowledge of chemistry was required. He confessed that, speaking as an outsider, he did not understand why it was that Germany was not only able to manufacture all the chemists she needed herself, but also to export to different parts of the world fifty chemists for every one who was exported by this country. He ventured to suggest, speaking in all humility, that there was a large field in this direction for the youth of England, if scientifically inclined. He thought it probable that most of those present who were practically acquainted with technical education would agree with him that they had not done nearly as much in this matter—and chemistry was an example of it—as they ought to do and would have to do. A great deal had been done in the past ten or twenty years; but they began late, and they had not yet caught up some other nations, and much had still to be done in this country in order to provide the facilities that were needed to furnish their sons with the knowledge that was necessary to enable them to carry on the commercial business of the country. The City and Guilds Institute had in the most munificent manner spent on its technical colleges in the course of the past eighteen years about half a million out of the funds over which it had control; but could they go on relying upon private munificence so much as they had done for the purposes of technical education? He ventured to think that the time had come when there should be some system supported by funds, if necessary, of some public nature by which colleges should be founded in the great centres where they were needed, and branch colleges of a similar description in smaller places where they were wanted. The whole scheme of technical education seemed to him to have come to the point at which it required some further consideration. In connection with this subject one had often to speak of Germany and Switzerland, but he was quite sure that they did not speak of them in any spirit of jealousy, but, on the contrary, in a spirit of admiring emulation of their work. They must take what they could that was best from those countries and adopt it, and leave the latter to act in a similar manner towards this country.

SCIENTIFIC SERIALS.

American Journal of Science, January.—A new harmonic analyser, by A. A. Michelson and S. W. Stroud. This is an instrument designed to sum up as many as eighty terms of a Fourier series, or to analyse a given curve into its original series. The pen which traces the curve is worked up and down by a lever controlled by a spring. This spring is stretched by an excentric, which imparts a "simple harmonic" variation to the force. The stretching is resisted by another spring. Eighty such elements are connected together, with one resisting spring to counterbalance the sum of the elementary springs. The pen therefore moves in accordance with the sum of the elementary periodic motions. The authors obtain by this machine the mathematical series representing the profile of a human face.—A new form of physical pendulum, by J. S. Stevens. The error introduced into the ordinary physical pendulum by the fact that the knife-edges and clamp affect the moment of inertia may be eliminated by boring a hole into the rod and screwing the knife edges a little way in, so that they offset the mass of brass bored out.—The Protostegan plastron, by G. R. Wieland. This is a restoration of the plastron of two specimens of the turtle described before as *Archelon ischyros*.—Phosphorescence produced by electrification, by J. Trowbridge and J. E. Burbank. When a piece of fluorspar is first exposed to the action of X-rays, and subsequently heated, it shows a bright phosphorescence. The same phenomenon may be produced by exposing the mineral to an electric brush discharge, and subsequently heating it. It is probable, therefore, that the X-rays produce an electrification of the fluorspar.—On iron meteorites, as nodular structures in stony meteorites, by H. L. Preston. It is an important fact that of over 100 falls and finds of siderites or iron meteorites but nine have been seen to fall, while of the aerolites or stony meteorites of over 400 falls and finds, more than one-half have been seen to fall. The author gives several reasons in support of the view that the siderites are merely the crystallised metallic nodules contained in the larger and more conspicuous stony meteorites.

SOCIETIES AND ACADEMIES.

LONDON.

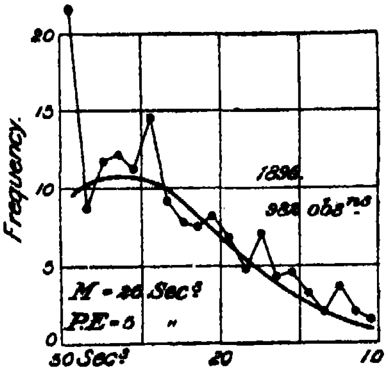
Royal Society, December 13, 1897.—"An Examination into the Registered Speeds of American Trotting Horses, with Remarks on their Value as Hereditary Data." By Francis Galton, D.C.L., F.R.S.

It is strange that the huge sums spent on the breeding of pedigree stock, whether of horses, cattle, or other animals, should not give rise to systematic publications of authentic records in a form suitable for scientific inquiry into the laws of heredity. An almost solitary exception to the disregard shown by breeders and owners, of exact measurements for publication in stud books, exists in the United States with respect to the measured speed of "trotters" and "pacers" under defined conditions. The performance of one mile by a trotter, harnessed to a two-wheeled vehicle, carrying a weight of not less than 150 lbs. inclusive of the driver, in 2 minutes 30 seconds qualifies him for entry in the "Trotting Register," giving him, as it were, a pass-degree into a class of horses whose several utmost speeds or "records" are there published.

The system of timing was first put into practice more than fifty years ago, and has since been developed and improved. In 1892 a considerable change was made in the conditions by the introduction of bicycle wheels with pneumatic tyres, which produced a gain of speed, the amount of which is much discussed, but which a prevalent opinion rates at 5 seconds in the mile. Thenceforward the records are comparable on nearly equal terms. All trotting performances up to the 2′ 30″ standard are registered in the large and closely printed volumes of "Wallace's Year Book," published under the authority of the American Trotting Association. Vols. viii.-xii. refer to the years 1892-6, and it is from the entries in these that the following remarks are based.

The object of my inquiry was to test the suitability of these trotting (and pacing) records for investigations into the laws of heredity. I had to determine whether the observations fell into a tolerably smooth curve; and, if so, whether that curve was a tolerable approach to the normal curve of frequency. In the latter event the observations would fall into line with numerous anthropometric and other measures which have been often discussed, and which, when treated by methods in which the arithmetic mean is employed, yield results that accord with observed facts.

I had 5705 extracts made from the entries published in the Year Books for the five years 1892-6. It was tedious work, and I thought it unnecessary to repeat it to check the results, being satisfied after some examination that they were quite accurate enough for general conclusions. They were arranged in columns; the first to the left contained entries of all observations recorded as 2′ 29·0″, 29¼″, 29½″, or 29¾″; that is of all under 2′ 30″ down to 2′ 29″ inclusive. The second column referred to 2′ 28″·0, 28″¼, 28″½, and 28″¾, and so on with the rest. These were then reduced to percentages and diagrams were drawn from them, of which the following, for the year 1896, is one; it will serve as a fair sample of the other four.



If divided by the eye into imaginary columns corresponding to those in the tables, the point representing the sum of the observations of 2′ 29″·0′, 29″¼, 29″½ and 29″¾ will be found in the middle of the first imaginary column, that is to say it stands vertically above the point that lies half way between 29 and 30 on the scale along the base. The dots are connected by thin lines to show the trace or curve of the observations. The smooth curves are those of normal frequency, calculated from the values of the mean (M) and of the probable error (P.E.), which are given in the diagrams.

Leaving aside for the moment the strange pinnacle that rises on the extreme left of every diagram, we see that the traces of the rest of the observations run very roughly, but not intolerably so. In each diagram they seem to be disposed about a fundamentally smooth curve. Considering the smallness of the interval, namely, only one second, that separates the observations assigned to each pair of successive columns, together with the experience derived from other kinds of statistical curves, it seems to me that the run of the observations is good enough to certify their general trustworthiness. As regards the pinnacle it is a different matter, and is one which when beginning work, as I did, on the 1892 entries only, was very perplexing. However, by persevering with the other years, it became increasingly plain that the pinnacle was a false maximum; in 1896 it was certain that the true maximum lay well within the portion of the curve included in the diagram. The explanation of the pinnacle then became obvious[1]; it was that the tolerance granted to those horses who failed by only a little to qualify themselves, was extended considerably beyond the quarter second for which I was prepared. The cases of 2' 30·0" were few; they do not appear in the diagram, but their addition would be quite insufficient to remove the difficulty. If the pinnacle were distributed among *two* adjacent columns outside and to the left of the diagram it would smooth away the incongruity, so I suspect that cases of "under 2' 32" and down to 2' 30"" are habitually rated at a trifle less than 2' 30". Consequently I had no hesitation in wholly disregarding the entries that helped to make the pinnacle, namely, the whole of those contained in the first column to the left in every one of the diagrams. The course thereupon became clear and straightforward. I estimated the position of the mean value for each year, from inspection of the curve of that year, allowing myself to be somewhat biassed in estimating its point of culmination by the curves of the adjacent years; similarly as to the probable error. Now that the curves are drawn, I see that somewhat better fits might have been made, but they are close enough to show the existence of a fair amount of correspondence between the observed values and those calculated according to the law of normal frequency. It is near enough to remove hesitation in working with the arithmetic mean.

I now come to the fundamental purpose of this memoir, which is to point out the existence in the registers of the American Trotting Association, of a store of material most valuable to inquirers into the laws of heredity, which accumulates and increases in value year by year. But it seems to me hardly worth while to discuss hereditary influence on speed in horses, unless the records of at least their sires and of their dams, and those of each of their four grandparents, as well as their own record, are all known. Even in this case (according, at least, to my own theory) one quarter of the hereditary influences are unknown and have to be inferred. It is practically impossible to make an adequate collection of the names of horses who fulfil the above conditions out of the entries in the "Trotting Register," each search requiring many cross references and occupying a long time, while the number of futile searches before attaining a success is great. On the other hand, the breeders and possessors of these notably bred horses must be familiar with the required facts, and would assuredly be delighted to have them known. There need, therefore, be little difficulty in obtaining materials for the much desired table. In the meantime I am sending circulars to the chief breeders in America, in hopes of making a start.

The great need for genealogical data of an exact numerical kind, by those who prosecute inquiries into the laws of heredity, is the justification that I offer for submitting these remarks to the Royal Society.

Physical Society, January 21.—Mr. Shelford Bidwell, President, in the chair.—Prof. Fitzgerald exhibited some photographs by Mr. Preston in illustration of the Zeeman effect, for various cases, including those of iron, cadmium, zinc, and sodium. These photographs and the method of obtaining them have already been described. The cause of doubling is now attributed by Prof. Fitzgerald to absorption by the surrounding vapour. In a particular case he examined a double line that exists in one of the photographs. Under the polariser the two lines are at first distinctly seen; but when the polariser is turned, a thin line appears in the middle, and this central line is, therefore, circularly polarised in a direction opposite to that of the outer pair of lines. The reason for the appearance of doubling in the first position of the polariser is that the central line is there completely absorbed out by the surrounding vapour.—Prof. Oliver Lodge then gave a communication concerning his work on "Electric Signalling without Connecting-wires." From the nature of the oscillatory disturbances emanating from any of the customary forms of Hertz vibrator, syntony has hitherto been only very partially available as a means for discriminating between receivers. There is in fact so rapid a decrease in the amplitude of the vibrations that almost any receiver can respond to some extent. Discrimination by syntony is possible with magnetic systems of space telegraphy where the magnetic energy much exceeds the electric, *i.e.* as between two separated inductive coils; and by the use of such coils, appropriately applied, the author has been able to attain fair syntony even with true Hertz waves, *i.e.* he has constructed spark-gap oscillators, with sufficient persistence of vibration, and syntonised resonators. The "coherer" principle can be applied to either a purely magnetic or to the Hertzian system. It was first used by Prof. Lodge in devising lightning-guards, and afterwards in his magnetic system of telegraphy by inductive circuits, each in series with a Leyden-jar; a pair of knobs in near contact, or other over-flow gap, being provided in the receiving apparatus. This was the first meaning of a "coherer" in the electrical sense as used by Prof. Lodge. It referred to a *single* contact between two metal knobs. The term has since been extended by others to the filings-tube of M. Branly, and some confusion has arisen, for M. Branly does not consider that simple coherence and break explains fully the behaviour of his instrument. Prof. Lodge is disposed to agree, for he finds that the resistance of almost any form of coherer varies in rough proportion to the received impulses, and that there are other peculiarities (to be mentioned later). He is, therefore, inclined to think that the action cannot after all be entirely explained as due to mere "welding," but that there is something more to be learnt about it. The sensitiveness of a coherer depends upon the number of loose contacts; it is a maximum for a single contact, *i.e.* for a needle-point lightly touching a steel spring. With this sensitive coherer, hardly any "tapping-back" is required for decoherence, but it wants delicate treatment when properly adjusted, and the greatest current through it should not approach a milliampere. On the other hand, a Branly tube rather improves under rough treatment; in such a tube the author prefers to use iron filings in the best possible vacuum; brass, too, is very good, but rather less easy to manage. Aluminium is thoroughly bad, and gold, for an opposite reason, will not work—its surface is too clean. Points, or small surfaces for making contact with the filings, are better than large surfaces. The usual method of connecting the coherer across the gap of an ordinary Hertz receiver, in parallel with the telegraph instrument and battery, has the unavoidable objection that they shunt away part of the received oscillations. With the syntonic receiver of Prof. Lodge, which contains no gap, but a closed wire coil instead, this difficulty no longer exists; for the coherer can now be in series with the detecting instrument, and in so far as these obstruct the oscillations they may be shunted out in various ways, as the author describes. The main feature of his new syntonised vibrators is this self-inductance coil, whose function it is to prolong the duration of the oscillations, and thereby to render syntony possible. Although such a coil acts disadvantageously in so far as it possesses resistance, the resistance does not increase so fast as the self-induction. The coil should consist of thick copper of highest conductivity, and it should have maximum inductance for given resistance. For similar reasons, the capacity-areas should also be of highest conductivity, their dimensions should increase outwards from the spark-gap, as triangles. The receiver must have no gap, it should be accurately bridged over when a transmitter is used as receiver. The limit of speed of response depends upon the telegraphic instrument. Dr. Muirhead adapted a siphon-recorder to the purpose, because it is one of the quickest responders; he arranged it so that it could be used with intermittent currents direct. Under these intermittent impulses the siphon trembles; and instead of the ordinary siphon-signals, the slip is marked with dots and dashes. Constant mechanical tremor is usually employed for decoherence, but the author finds that decoherence can be brought about by electrical means, without any mechanical tremor, by connecting the coherer momentarily to a circuit less effective as a collector than that of the proper capacity-areas of the syntonised receiver. The battery and galvanometer detector-circuit may be used for this purpose, the coherer being momentarily connected to it, and while so connected letting it experience an impulse from a distance. Prof. Lodge has designed a revolving commutator by means of which the coherer can be rapidly changed over from the resonating circuit to the instrument-circuit, and finally to the "tapping-back" apparatus. A coherer is more sensitive when thus isolated and exposed to the full influence of the received oscillations; the subsequent detection of the effect by altered connections is very convenient for laboratory measurements. A diagram of a series of plotted measurements showed that the resistance of an undisturbed filings-tube is approximately a direct function of the intensity of the received stimulus, whether successive stimuli increased or decreased in strength. This electrical process of "tapping-back" is to be depended upon, but the process long continued fatigues the tube until a mechanical shake is employed to restore it. Large size apparatus made by Dr. Muirhead for actual distant syntonic work was exhibited, and means were shown for protecting and isolating the coherer when its receiving areas were being used as emitters; also a switch used for changing at one moment all the connections from "sending" to "receiving." Prof. Threlfall said he had come to the same conclusion as Prof. Lodge as to the advisability of diminishing the number of contact-points in the coherer. He had endeavoured to produce longer and more persistent waves, and thus to set afield greater effective energy. It was desirable to keep the waves as parallel as possible. He thought there was some probability that the wave-fronts could be altered and rendered more conformable by a process of diffraction. Mr. Rutherford also had found it best to work with long waves. He fully appreciated the advantage of increasing the capacity of the oscillator by extending the surface of the metallic plates. Mr. Campbell-Swinton asked whether experiments had been made to verify Hertz results as to the influence of reflectors behind oscillators and receivers. He had found them disadvantageous. A single wire behind either apparatus seemed partially to annul the effect. He also asked whether Prof. Lodge had observed the extraordinary sensitiveness of coherers to small changes of current in neighbouring circuits. Prof. Lodge, in reply, said he had observed the sensitiveness to slight sudden variations of current referred to by Mr. Campbell Swinton; for instance, when electric lamps were switched on or off. The effect of mirrors had been studied by Prof. Fitzgerald. They required to be of large dimensions as compared to the oscillator and receiver, otherwise the true reflections were not obtained. Dr. Silvanus Thompson afterwards exhibited a Tesla oscillator. This apparatus is intended to replace the two induction coils and spark-gap arrangements used by Mr. Tesla for high frequency experiments. It consists of an induction coil with a separate self-inductance coil in the primary circuit. This self-inductance coil is also used as an electromagnet for the separate interrupter of the primary circuit. A condenser is connected between one end of the primary coil and one terminal of the interrupter, so as to include both of them between its terminals. The primary is a single turn of copper strip, six inches wide. The secondary is one layer of thick wire; each turn separated from the next by an air space. The supply current, about half an ampere, may be taken from the electric-light mains at almost any voltage from 50 to 200, direct or alternating. Prof. Lodge said it would work quite well at 10 volts. He pointed out also that if the straight discharge-rods at the spark-gap were free to slide, the discharge drove them back into their sockets. Prof. Fitzgerald said it was stated at Toronto that the spark was broken at the interrupter when the condenser was charged, and that by the time the condenser was ready to discharge, the contact at the interrupter had been made again. It seemed to him that the condenser discharges and surgings must take place at a rate far higher than the period of the mechanical movement of the interrupter. The condenser charges and discharges were very rapid. It was not what is ordinarily called the "time constant" that was involved, for that only referred to constant voltage. Here the voltage was changing very rapidly indeed. Prof. Herschel asked if such an apparatus was suitable for work with Röntgen rays. Dr. Thompson, in reply, congratulated Mr. Tesla upon the perfect working and compactness of his invention. The present form was not suited for Röntgen ray experiments, but Mr. Tesla had designed a special coil that was excellent for that purpose. —The President proposed votes of thanks, and the meeting was adjourned until February 11.

---

[1] I should like to take the opportunity afforded by the appearance of an abstract of my memoir in NATURE to correct a questionable suspicion, namely, that the pinnacles in the diagrams are due to tolerance shown towards horses who failed by a very little to qualify for the much-coveted rank of standard trotters. I am assured on excellent authority that the strict conditions of timing make this impossible (among other reasons there are three timers). On the other hand, there is a vast competition *just* to pass the 2' 30" limit; and when a horse has done so, his owner often does not care to train him for racing, but rather to utilise him at once for breeding or other purposes. The question is too complicated to discuss here at length. Suffice it that the 2' 29" to 2' 30" records are not homogeneous with the rest, and should be discarded as I proposed.—F. G.

PARIS.

Academy of Sciences, January 24.—M. Wolf in the chair. —On the reduction of some double integrals, and on a new invariant in the theory of algebraic surfaces, by M. Émile Picard.—Addition to a preceding note on the Zeeman effect, by M. A Cornu. Some results of measurements showing that the magnitude of the separation produced increases with the refrangibility of the ray.—On the conditions of formation of alkaline carbides, and the carbides of magnesium and of the alkaline earths, by M. Henri Moissan. Metallic potassium, if left for a long time in acetylene, slowly but completely decomposes the gas giving hydrogen and C_2HK. Sodium gives a similar compound when sealed up with liquid acetylene, and this C_2HNa, heated in a vacuum, gives up pure acetylene, leaving sodium carbide C_2Na_2 behind; at a red heat this is decomposed into carbon and sodium. The potassium compound behaves similarly, neither sodium, potassium, nor magnesium carbides being able to exist at the temperature of the electric furnace.—Histological mechanism of cicatrisation; on true immediate reunion, by M. L. Ranvier. In wounds caused by cutting the cornea of the rabbit, two modes of closing up of the tissue can be noted, an immediate synaptic joining, and a true immediate joining, the former due to the cuts being filled with epithelial cells arising from the neighbouring epithelium, and the latter noticeable only in wounds forty-eight hours after the incision had been made, and where, owing to the lips of the cut happening to touch, no epithelial cells had penetrated.—The enlargement of the right auricle of the heart during inspiration demonstrated by radioscopy, by M. Ch. Bouchard.—On the fourth voyage of the *Princesse-Alice*, by S.A.S. Albert I., Prince of Monaco. The chief work was done on the western coast of Morocco, round Madeira and the Azores, and comprised sounding operations, together with zoological study of the fauna of the Princesse-Alice bank. A chart of this bank accompanies the paper.—Remarks by M. Edmond Perrier on his work on animal colonies and the formation of organisms.—Shooting-stars in the months of November and December 1897, observed at Basse-Terre (Guadeloupe), by M. Ch. Duprat.—On the development of uniform or holomorphic functions in any field, by M. Paul Painlevé.—On the types of increase and on complete functions, by M. Émile Borel.—On systems of partial differential equations analogous to equations of the first order, by M. Jules Beudon.—On the geometry of magnetic fields and of motion with two degrees of freedom in a plane or on a sphere, by M. René de Saussure.—Law of deformation of commercial metals, by M. Marcel Brillouin. A mathematical expression is given which includes all the known facts regarding permanent changes of shape in metals.—On an interference spectroscope, by MM. Ch. Fabry and A. Perot. The method consists in observing rings produced by transmission through a layer of air contained between two perfectly parallel silvered glass faces. Full details of the adjustments necessary are given in the present paper.—On the part played by diffraction in the effects produced with gratings, by M. Ch. Féry.—Study of chemical and physical equilibria by the osmotic method, by M. A. Ponsot.—On the law of mixture of gases, by M. Paul Sacerdote, giving the experimental results of mixing equal volumes of gases. The observed changes of pressure for a mixture of nitrous oxide and carbon dioxide, and of the latter gas with sulphur dioxide, are compared with those deduced from the densities by M. Leduc. The results of the two methods are in general agreement.—On the separation of thorium and the cerite earths, by MM. G. Wyrouboff and A. Verneuil.—The method proposed is based upon the fact that in a mixture of nitrates of the rare earths, as free as possible from excess of acid, heating with excess of hydrogen peroxide to 60° completely precipitates all the thoria in the solution.—Hydramides and the isomeric glyoxalidines, by M. Marcel Delépine. A thermochemical paper.—Researches on ouabaine, by M. Arnaud.—Synthesis of terebic acid, by M. E. E. Blaise.—Manufacture of acetone oil, in particular of methyl-ethyl-ketone, by means of the liquors from the desuintage of wool, by MM. A. and P. Buisine. The calcium salts of the mixture of fatty acids obtained from wool is submitted to dry distillation. The resulting liquid yields on fractionation 60 per cent. of methyl-ethyl-ketone. —On the estimation of gastric juice, by M L. Cordier. The free acid is converted into lithium chloride by treatment with lithium carbonate, and this separated from the sodium chloride by extracting the incinerated residue with a mixture of equal parts of absolute alcohol and dry ether, in which the lithium chloride only is soluble.—Ergographical experiments for measuring the maximum power of a muscle regularly stretched, by MM. André Broca and Charles Richet.—The fungus *Sporotrichum globuliferum*, by M. Trabut.—On the anhydrous calcium sulphate produced by the complete dehydration of gypsum, by M. A. Lacroix. The dehydration of gypsum gives rise to a calcium sulphate dimorphous with anhydrite, probably triclinic. When the drying was not quite carried to completion another form of crystal was observed, possibly $2CaSO_4.H_2O$.—On the Callovian of Woëvre, by M. René Nicklès.—On the third international ascent of experimental balloons, by M. Ed. Stelling. Two ascents were made, one with two observers, the other balloon carrying self-registering instruments only. The temperature variation with the height is given in full.

DIARY OF SOCIETIES.

THURSDAY FEBRUARY 3.

THE BOOK OF THE DEAD.

The Book of the Dead. The Chapters of Coming Forth by Day. The Egyptian Text according to the Theban recension in hieroglyphic edited from numerous papyri, with a translation, vocabulary, &c. By E. A. Wallis Budge, Litt.D., D.Litt., F.S.A., Keeper of the Egyptian and Assyrian Antiquities in the British Museum. In three volumes. Pp. cciv + 354; xl + 517; vii + 386. (London: Kegan Paul, 1898.)

IN the first of the Gifford Lectures for 1896, Prof. Tiele gave an admirable sketch of the method of work which the student of the modern science of religion must pursue if he is to achieve any lasting results. The process is a long one, for he must acquaint himself with the whole field of religion and be master of the material with which he works; and he should, in the Professor's opinion, have taken part himself in exploring and clearing the ground, and have studied at least two religions in the original sources. We fear that for many workers in this comparatively recent field of study the lecturer's words came as a counsel of perfection. But even working by Prof. Tiele's high standard, the range of study is so broad that the student of religion can obtain only a small proportion of his information at first hand, and for the greater part of his material must make use of the labours of others; in the wider field of anthropology, which in one sense includes the science of religion—though Prof. Tiele would not here agree with us—the range of study is still more extensive. For information respecting the culture, customs and beliefs of savage and undeveloped races of the present day, the student must consult the works of travellers, missionaries, and trained collectors and explorers; while for the beliefs of the ancient nations of the world, he necessarily to a great extent depends on the translations made by scholars who have devoted their energies to the interpretation of the sacred books and documents that have come down to us. Prof. Max Müller's "Sacred Books of the East," for example, supply him with ample material in his examination of the beliefs of the ancient Aryan races; though it must be admitted the religious works of many other ancient nations still need trustworthy translations. The want of such a translation of the great religious work of the ancient Egyptians has long been felt, but it is now met by Dr. Wallis Budge's translation of the "Book of the Dead."

The importance of the "Book of the Dead" in its bearings on the religion of the ancient Egyptians cannot be over-estimated. Including as it does their whole system of belief, it is our principal source of information on the subject. It is true that collections of moral precepts, hymns and prayers to the gods, mythological texts and legends, all contribute something to our knowledge; but the collection of compositions, to which the title "Book of the Dead" has been applied, is in itself the embodiment of the Egyptian's creed, and from it alone can any true understanding of his religion be obtained. For many years the work was known only in publications of single papyri of different periods, the most important of which was that published in 1842 by Lepsius, whose numbering of the chapters has been retained by all subsequent editors. It was not until more than thirty years later that any complete edition of the work was contemplated. In 1874, at a meeting of the International Congress of Orientalists, a scheme for such an edition was projected, and M. Naville undertook the work. Confining himself to papyri of the eighteenth to the twentieth dynasties, during which period the finest papyri of the "Book of the Dead" were written, he in 1886 produced a critical edition of the Theban recension of the work, which he published with an introduction but no translation. In the new edition of the work just issued, Dr. Budge has added considerably to M. Naville's text by using some unique papyri—which have been acquired during recent years by the British Museum. In another volume he has published a complete vocabulary to the text, which will prove of great service to Egyptologists. But the volume which marks the greatest advance on previous editions, and with which we are here concerned, is the one in which Dr. Budge gives a complete translation of the text, a work that has long been needed, but which he is the first to have accomplished; the translation is preceded by an introduction, in which he deals with the origin, aim and contents of the "Book of the Dead," and states the conclusions at which he has arrived as the result of many years of study.

The many points suggested by such a work cannot be adequately treated within the limits of a review, and it will be necessary to confine our attention to certain parts of the introduction where Dr. Budge has developed his theories with regard to the "Book of the Dead." One of the most important chapters of the introduction is that devoted to the history of the "Book of the Dead." The four main recensions of the work have long been recognised by scholars, that of the Old and Middle Empires, the Theban version, the version of the twentieth dynasty, and the text of the Saite and Ptolemaic periods. Dr. Budge, however, strikes out a novel line in his sketch in the history of the work, by going back beyond the time of the pyramid-builders of the fifth and sixth dynasties, and seeking in the remains of prehistoric Egypt the causes that led to the subsequent development of the work. In the graves recently excavated at El-'Amrah near Abydos, which possibly belonged not to the Egyptians themselves, but to their predecessors in the land, were found skeletons showing traces indicating that the bodies to which they belonged had been embalmed. This custom of preserving the bodies of their dead, which we thus find in existence at the dawn of Egyptian civilisation, lasted without a break through the whole period of the nation's history down to the fourth century A.D. In what way it gave rise to the "Book of the Dead" is best described in Dr. Budge's own words:—

> "As time went on the embalming of the dead was performed in a more elaborate manner, and at the same time the last resting place of the mummified body was chosen more carefully and wrought with greater attention. At a very early period the wealthy discarded the use of holes in rocks and caves as tombs, for in these the bodies were accessible to the attacks of enemies, and wild animals and serpents; and the same objection was,

naturally, made to shallow hollows made in the limestone and covered over with slabs of the same material, and also to the vaulted, crude brick graves which were commonly in use in the early dynasties. The place of these was taken by pyramids built of stone, and by many-chambered tombs hewn in the living rock. Experience, however, soon showed the Egyptian that the most carefully constructed tomb was incapable of preventing damp-rot or dry-rot and decay, and that some other power besides his own must be invoked to prevent the destruction of his body, which, though needing longer time to accomplish, was as effectually performed by these means as by the tooth of the wild animal or serpent, or by the hand of the enemy. At this stage the aid of the professional religious man or priest was called in, and the task of finding means to prevent rot and decay was entrusted to him. There is little doubt that when the body was laid to rest in the tomb, the priest pronounced certain words or formulæ or prayers over it, and it is probable that the recital of these words was accompanied by the performance of certain ceremonies. Whatever these formulæ were they formed the foundation of the 'Book of the Dead' of later Egyptian times."

This is a reasonable theory as to the origin of the work, and we think Dr. Budge is also justified in the further assumption that though these formulæ were first only recited, they were afterwards written down by the priests with a view to preserving them, and that the custom of inscribing portions of them on the walls of the tomb, and of writing them on the coffin and on papyri deposited in the tomb, followed from the subsequent belief that their efficacy was thus insured for the benefit of the deceased. In a series of eighteen plates Dr. Budge has illustrated the changes of form which the "Book of the Dead" underwent in the long course of its development from the time when we find it on the walls of the pyramids at Ṣakkāra, to its final deterioration in compositions of the Roman period. Its culmination in the illuminated papyri of the eighteenth dynasty is illustrated by means of three very beautiful coloured plates representing portions of the famous papyrus of Ani in the British Museum.

Another section of the introduction, which will prove useful to any one who attempts to understand the "Book of the Dead," is that which Dr. Budge devotes to its object and contents. He here classifies the chapters according to their subject-matter, and we thus gain an insight into the underlying unity of the work; for, though its chapters represent beliefs belonging to all ages in the life of the nation, the aim underlying them all is in some way or other to benefit the deceased. "They were intended," says Dr. Budge, "to give him the power to have and to enjoy life everlasting, to give him everything which he required in the life beyond the grave, to ensure his victory over his foes, to procure for him the power of going whithersoever he pleased and when and how he pleased, to preserve the mummy intact, and finally to enable his soul to enter into the bark of Rā or into whatever abode of the blessed had been conceived of by him." We have not space to enter into any adequate discussion of the exact nature of the ancient Egyptian's belief in a resurrection and a judgment, or to consider how far he advanced in his conception of monotheism. He never outgrew his belief in magic, and while undoubtedly advancing in his notions of a spiritual existence, he did not discard the more primitive tenets of an earlier age. It is constantly necessary to bear this fact in mind in reading the "Book of the Dead." By his translation of the work, Dr. Budge has earned the gratitude of all students of the science of religion, for he has thereby placed within their reach a wealth of fresh material. For the benefit of those who are not Egyptologists, we are glad to note that the introduction and translation are issued as an independent work, and sold separately from the volumes containing the hieroglyphic text and vocabulary.

FERNS.

Die Farnkräuter der Erde. By Dr. H. Christ. Pp. viii + 388; with 291 figures. (Jena: Gustav Fischer, 1897.)

SINCE the publication of Baker's "Synopsis Filicum" in 1873 (Dr. Christ makes no mention of John Smith's "History of Ferns," 1877) no complete systematic account of the ferns has appeared, so that there is room for a work which embodies the more modern discoveries in this subdivision of plants. During this interval, Dr. Christ says a number of new species have become known, and, owing to the researches of G. Mettenius into the general structure of this subdivision, additional materials are to hand for the elaboration of a more natural arrangement. He believes that the older authors, including Hooker, too rigidly limited themselves to the consideration of the sorus and indusium for purposes of classification. Influenced by these reflections he has been led to change the arrangement adopted in the "Synopsis Filicum," in several cases, for what he regards as a more natural grouping. His view of the matter is, however, sometimes open to doubt. The position he assigns to the genus Loxsoma may be taken as an example of one of such alterations. He transfers it from the Hymenophyllaceæ to the Polypodiaceæ, apparently because its leaves have several layers of cells and are furnished with stomata. On the other hand, its sorus and indusium resemble those found in the Hymenophyllaceæ. An alteration like this may be defended or assailed according to the personal feeling of each systematist, and its criticism will depend on what morphological value each individual places on the various diagnostic characteristics. But it appears that the structure of the leaves, taken alone, would often be misleading. The leaves of a few of the Hymenophyllaceæ are several layers thick; while in the Osmundaceæ—a group, for the most part, possessed of stout leaves—Leptopteris has delicate and filmy leaves without stomata. The existence of the fossil *Palæopteris hibernica*, which had leaves resembling Loxsoma, but in other respects belonging to the Hymenophyllaceæ, renders the connection of the latter genus to that class of ferns more probable.

Again, Dr. Christ removes *Ceratopteris thalictroides* (a plant which, by the way, is omitted in the index, but described in the text) from the Polypodiaceæ into a separate class, the Parkeriaceæ, without, it might be thought, sufficient reason. The anomalies in the structure of its vegetative organs may well be accounted for by its watery habitat, unique among the filices.

The two species of Matonia are placed in a separate group, as Baker suggested.

It is disappointing to find that no mention is made of the gametophyte in ascertaining the relations of the classes to one another; although its systematic value has been shown in several cases. It is quite possible that the position of doubtful genera, such as Loxsoma, will only be understood when its gametophyte has received complete investigation. The omission, however, may be justified owing to the practical difficulties of obtaining the sexual generation for systematic purposes.

The introduction is short and is chiefly occupied with explaining the scope of the book; and it seems a pity that a writer, with so much knowledge of the ferns, did not give more space in his work to general considerations. At the end, however, Dr. Christ refers to the marked manner in which ferns belonging to different classes resemble one another: thus, Diacalpe—a member of the Aspidiaceæ—has a sorus very like that found in the Cyatheaceæ. In the Polypodiaceæ some genera have the sorus situated at the tip of the veins and projecting beyond the margin of the leaves, in this reminding us of the Hymenophyllaceæ. It is fanciful, if not inaccurate, to see in this position of the sorus a resemblance to the mosses. Other interesting examples are given; but it is unfortunate that the author applies the term "mimicry" to these instances of parallelism in related groups. Such an application of the term must only lead to confusion.

The descriptions of the genera and species are marked by their precision and lucidity, and the numerous illustrations, which were specially prepared for this work, are characteristic drawings, though sometimes roughly executed. The appearance of such a book will be welcomed by systematists interested in the ferns containing, as it does, the more recent results of Baker, Hooker, Kuhn, Luersson, Prantl, &c., and those of Dr. Christ himself.

It might be suggested that if the key of genera, which precedes the detailed diagnoses of genera and species, was furnished with references to the pages on which the diagnoses are to be found, an addition would be made to the usefulness of the book. H. H. D.

SCIENCE IN FICTION.

The War of the Worlds. By H. G. Wells. Pp. 303. (London: William Heinemann, 1898.)

MANY writers of fiction have gathered material from the fairy-land of science, and have used it in the construction of literary fabrics, but none have done it more successfully than Mr. H. G. Wells. It is often easy to understand the cause of failure. The material may be used in such a way that there appears no connection between it and the background upon which it is seen; it may be so prominent that the threads with which it ought to harmonise are thrown into obscurity; or (and this is the worst of all) it may be employed by a writer whose knowledge of natural phenomena is not sufficient to justify his working with scientific colour. Mr. Wells makes none of these mistakes. Upon a groundwork of scientific fact, his vivid imagination and exceptional powers of description enable him to erect a structure which intellectual readers can find pleasure in contemplating. "The Time Machine"—considered by the majority of scientific readers to be Mr. Wells' best work—showed at once that a writer had arisen who was not only familiar with scientific facts, but who knew them intimately enough to present a view of the future. "The Island of Dr. Moreau," though decried by some critics, is a distinctly powerful work, and the worst that can be said of it is that the pabulum it provides is too strong for the mental digestion of sentimental readers. But in several respects "The War of the Worlds" is even better than either of these contributions to scientific romance, and there are parts of it which are more stimulating to thought than anything that the author has yet written.

The invasion of the earth by inhabitants of Mars is the idea around which the present story is constructed The planet is, as Mr. Percival Lowell puts it, older in age if not in years than the earth; and it is not unreasonable to suppose that if sentient beings exist upon it they would regard our world as a desirable place for occupation after their own globe had gone so far in the secular cooling as to be unable to support life. Mr. Wells brings the Martians to the earth in ten cylinders discharged from the planet and precipitated in Surrey. The immigrants are as much unlike men as it is possible to imagine, and only a writer familiar with the lines of biological development could conceive them. The greater part of their structure was brain, which sent enormous nerves to a pair of large eyes, an auditory organ, and sixteen long tactile tentacles arranged about the mouth; they had none of our complex apparatus of digestion, nor did they require it, for instead of eating they injected into their veins the fresh living blood of other creatures. Their organisms did not sleep any more than the heart of man sleeps; they multiplied by budding; and no bacteria entered into the scheme of their life. When they came to the earth they brought with them a means of producing a ray of intense heat which was used in connection with a heavy vapour to exterminate the inhabitants of London and the neighbourhood.

This bald outline does not, however, convey a good idea of the narrative, which must be read before the ingenuity which the author displays in manipulating scientific material can be appreciated. The manner in which the Martians are disposed of is undoubtedly the best instance of this skill. As the Martians had eliminated micro-organisms from their planet, when they came to the earth their bodies were besieged by our microscopic allies, and they were destroyed by germs to which natural selection has rendered us immune. This is a distinctly clever idea, and it is introduced in a way which will allay the fears of those who may be led by the verisimilitude of the narrative to expect an invasion from Mars. Of course, outside fiction such an event is hardly worth consideration; but that the possibility of it can be convincingly stated, will be conceded after reading Mr. Wells' story. A remarkable case of the fulfilment of fiction is furnished by the history of the satellites of Mars. When Dean Swift wrote "Gulliver's Travels" (published in 1726), he made the astronomers on the island of Laputa not only observe two satellites, but caused one of these to move round the planet in less time than the planet itself takes to rotate on its axis.

As every student of astronomy now knows, the satellites were not discovered until 1877, and one of them actually does revolve round Mars three times while the planet makes a rotation. The coincidence is remarkable; but it is to be hoped, for the sake of the peace of mind of terrestrial inhabitants, that Mr. Wells does not possess the prophetic insight vouchsafed to Swift.

In conclusion, it is worth remark that scientific romances are not without a value in furthering scientific interests; they attract attention to work that is being done in the realm of natural knowledge, and so create sympathy with the aims and observations of men of science. R. A. G.

OUR BOOK SHELF.

Introductory Course in Differential Equations. By D. A. Murray, B.A., Ph.D. Crown 8vo. Pp. xv + 234. (New York and London: Longmans, Green, and Co., 1897.)

Ordinary Differential Equations; with an Introduction to Lie's Theory of the Group of One Parameter. By James Morris Page. Crown 8vo. Pp. 226 + xviii. (London: Macmillan and Co., 1897.)

MR MURRAY's book is adapted to provide for students that knowledge of the subject of differential equations which they are likely to want in applications of mathematics to physics, and in the general courses in arts and science in "classical" colleges. The author is chiefly occupied with giving expositions of the devices usually employed in the solution of the simple differential equations which such students meet with, and he will be found a safe guide in these matters. He follows the plan, which most recommends itself to teachers, of omitting theoretical considerations, or postponing them until the student has had practice in carrying out the processes with which he must be acquainted before the theory can be understood. But he does not leave the reader altogether in the dark as to the underlying theory and the modern developments. These are considered near the end of the book in a series of notes, which ought to prove very useful to those who wish to know more about the subject than can be learned from the text. In one case, that of the integration of linear equations in series, the author has departed from his general practice of giving an account of the simple and particular rather than of the difficult and general. It seems unfortunate that he did not choose for discussion the forms of the series which satisfy such equations in the neighbourhood of ordinary points. When a second edition is called for he will do well to alter this, and to avoid such expressions as "concentric cylinders" and "consecutive curves." The book is well printed, and is adequately supplied with well-chosen examples, some of them relating to physical subjects; and it ought to prove of service both to those for whom it is primarily intended, and also to British students who have not time to master Forsyth's treatise, but wish to learn rather more about the subject than is to be found in Lamb's "Infinitesimal Calculus."

In several important respects Mr. Page's book differs considerably from most existing text-books on differential equations. It is not sufficiently elementary for students reading the subject for the first time, since it makes no attempt to supply that thorough drilling in the solution of linear equations with constant coefficients and other simple forms, which our Universities insist on as a preliminary test of proficiency. Those, however, who have passed beyond the threshold of the subject, and who wish to study the general machinery underlying the methods they have learnt, will find in Mr. Page's work the first attempt to present to English readers a concise account of some of Prof. Lie's important developments of the theory of transformation groups, by which he has shown that the usual methods are only applicable to such differential equations as admit of known infinitesimal transformations. A great many of the methods here described are due exclusively to Prof. Lie; the examples at the end of each chapter are, however, largely taken from existing text-books. A feature which strikes us as distinctly good, is the treatment together of simultaneous systems and the equivalent linear partial equation.

The two books before us are thus, to a great extent, complementary in scope. Starting with no knowledge of differential equations, a course of study first under Mr. Murray's and then under Mr. Page's guidance will lead the student by easy stages up to an insight into the Theory of Groups.

Nature Study in Elementary Schools; a Manual for Teachers. By Mrs. L. L. W. Wilson. Pp. xix + 262. Woodcuts. (New York: The Macmillan Company. London: Macmillan and Co., Ltd., 1897.)

THERE is a notion in this book—a sensible, practicable notion; and this is enough to distinguish Mrs. Wilson's lessons from the common run of school natural histories. Her aim is to stimulate the children to work for themselves; and now and then she succeeds in laying out really interesting work for them, as in the lessons on seedlings and on some common American trees. We recommend the book to the notice of enterprising teachers. In spite of very obvious defects, it may be a guide to better methods than those which prevail at this time. The great fault of the book is the feeble execution of an excellent idea. Many of the lessons do no sort of justice to the objects, and pass over without remark features which ought to arouse the curiosity of the children. We can hardly understand how any teacher could work through the thorn-apple with a class, and then write down so poor a description as that on p. 19. Many of the drawings, particularly those of insects, are too crude and hasty to be produced as examples even of what can be done in school. In the present writer's opinion the mythology and the poetical pieces are overdone. These things may be allowed to come in as extempore illustrations; but when they are laboured, they simply distract the attention and prevent the children from focussing their minds upon the objects.

A word as to the use of printed lessons. On no account should the book be produced in class; that would be to give the solution of the problems in advance. Nor should the teacher reproduce the very lessons given in the book, but devise lessons of his own upon the same lines. In this way the book now before us can be turned to excellent account. L. C. M.

Botanical Microtechnique: a Handbook of Methods of Preparation, Staining, and of Microscopical Investigation of Vegetable Structures. By Dr. A. Zimmermann, Privat-docent in the University at Tübingen. Translated from the German by James Ellis Humphrey, S.D. Pp. xii + 296. (Westminster: Archibald Constable and Co., 1896.)

MODERN advanced work in vegetable, as in animal, histology requires the aid of a refined and often complicated technique in order to render apparent the more difficult details of structure. The zoologist possesses at least one good treatise on methods; but until the appearance, in its English form, at the hands of Dr. Humphrey, of Zimmermann's excellent work, there was no advanced handbook available to a student unacquainted with German. The scope of the book is sufficiently indicated by the title, and under its new form can be confidently recommended to English-speaking students.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Bipedal Lizards.

I COMMUNICATED to NATURE, July 22, 1897, the intelligence that I had demonstrated by practical experiments that both the Australian Water Lizard (*Physignathus Leseuri*) and the Muricated Tree Lizard (*Amphibolurus muricatus*) shared with the Australian Frilled Lizard (*Chlamydosaurus kingi*) the singular faculty of running erect on its hind legs only. In that letter I refer to the as yet unconfirmed rumour that the Mexican Iguanoid Lizard (*Corythophanes Hernandeseyi*) also runs bipedally, and express the opinion that, judging from the close correspondence in general structure—more especially as regards the abnormal length of the hinder limbs—that exists between many of the American Iguanidæ and the Australian Agamidæ, it will probably be found that a corresponding bipedal mode of locomotion is shared by many allied members of the first-named family.

As a result of that communication and of a further ventilation of the subject in a paper recently read by me at the Royal Colonial Institute,[1] I have quite recently received an extensive and exceedingly interesting confirmation of my anticipations. Mr. Henry Prestoe, a twenty years' resident in the West Indies, writes me as follows:—"I have been struck by your remarks on the bipedal locomotion of the Frilled Lizard. It has occurred to me you would be glad to learn, if only in confirmation of your views, that with all the lizards—from the large Iguana, which lives in trees chiefly and is about five feet long when full-grown, down to the smallest mite one sees occasionally about the stones, I have ever seen running, the method of hurried locomotion is *bipedal*. The most familiar example is the so-called Diamond Lizard, common in the pastures and pleasure-grounds of Trinidad, 18 to 24 inches long, including the tail. The attitude results, when the progress is over a muddy surface, in footprints exactly like those of a small fowl, going lightly, and accounted in my mind years ago for the occurrence of bird-like footprints much further down in geological strata than birds are known to have existed. The motion of the legs of the Diamond Lizard, when running, is so rapid as to render them for the time invisible. But in the case of the large Iguana the case is different, and it takes an effort to get up into the slanting position which the Diamond and smaller lizards assume at once. Meantime the action or "swing" of the behind feet is that of an ordinary duck—accentuated—remaining grotesque in fact so long as the more or less erect position is kept up."

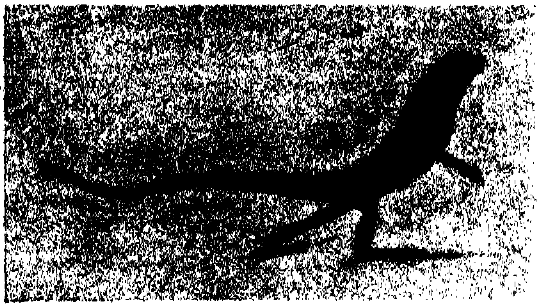

FIG. 1.—Leseur's Water Lizard (*Physignathus Leseuri*), running erect.

Mr. Prestoe has informed me of the further interesting fact that there are many figures traced on the rocks about the watershed of the Guianas, certain of which unmistakably represent a lizard, such as the Diamond species, running on two legs. A figure Mr. Prestoe has supplied me with as a fair reproduction of one of the rock scratchings corresponds in a noteworthy manner with the silhouette-like representation of Leseur's Water-lizard obtained by myself when taking an instantaneous photograph of the animal in its most characteristic bipedal attitude.

This phenomenon of bipedal locomotion, now shown to be common to many lizards that differ not only in their modes of life and widely separated habitats, but also in essential structural features, can scarcely fail to commend itself to the closer attention of the systematic biologist. When, as first reported by me, only a single species, *Chlamydosaurus kingi*, could be accredited with this remarkable mode of locomotion, it was interpreted as most probably representing a habit that had been independently and recently acquired. Now, however, the demonstrated fact of its widespread occurrence is clearly indicative of its inheritance from a remoter ancestry with whom bipedal locomotion also constituted a common method of progression. The question is, who were they?

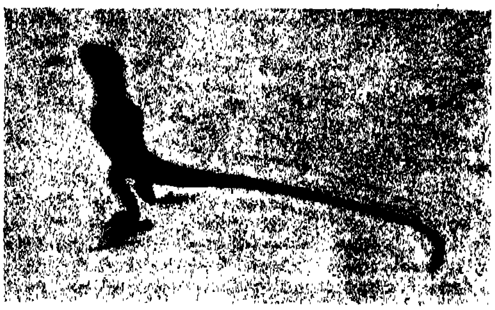

FIG. 2.—Australian Muricated Tree Lizard (*Amphibolurus muricatus*), running erect.

Apart from the foregoing considerations, I would suggest that the provision of conditions at our Zoological Gardens under which the many lizards possessing bipedal habits could exercise their singular but hitherto almost completely overlooked athletic accomplishments, would prove a great attraction to both naturalists and to the general public. Several varieties of these bipedal lizards are now on view in the Reptile House. They are at present, however, confined in relatively small cages, and, as I have demonstrated by practical experiments, it is essential for their display of bipedal locomotion that a level floor, with a free run of at least 20 or 30 feet, should be at their disposal.

Instantaneous photographs taken by me—but hitherto unpublished—illustrating characteristic attitudes assumed by *Physignathus Leseuri* and *Amphibolurus muricatus*, when running erect, are herewith reproduced.

W. SAVILLE-KENT.

The Glacial Period and the Irish Fauna.

MR. LAMPLUGH assumes (NATURE, January 13, p. 245) the correctness of the view that during the Glacial Period the basin of the Irish Sea was filled with an ice-sheet, and argues that my "interesting speculations" on the origin of the Irish fauna, in so far as they are based upon assumptions as to the glacial conditions of the Irish Sea, will therefore possibly not meet with much acceptance among geologists. That the Irish Sea, however, was filled with an ice-sheet during the Glacial Period is certainly not universally accepted among geologists. I think also, that it would have been more advantageous to us to hear Mr. Lamplugh's remarks, after having read in full my paper dealing with the origin of the Irish fauna, instead of the short abstract in NATURE. He would then have observed that I particularly avoided basing assumptions as to the origin of the Irish fauna on the glacial conditions of the Irish Sea. It has been rather too much the practice among some geologists of late, not only to assume the correctness of their theories as to the nature of the Glacial Period, but also to base thereon the probable course of events of the migrations of animals and plants. I have attempted, with a view to arriving at a more satisfactory conclusion on the origin of the British fauna, to found my deductions almost entirely on the presence in or absence from the British Islands of continental species. These conclusions are at variance with the views held by the, what we might call, extreme Glacial school of geologists.

In dealing with this subject, it seems to me, there is nothing gained in reiterating the same assumptions over and over again; and it really is immaterial whether the reindeer, the Irish elk, and dozens of other animals can or cannot cross ice. This does not affect the British fauna as a whole very much. The bulk of the English and Irish animals *must* have travelled to these islands on a land-surface which was not covered by ice, and how they did so and when, is the problem at issue. To attack this problem from a purely zoological point of view will, I think, be of great service to geological science, and will help to clear up many doubtful points as to the nature and cause of the Glacial Period.

---

R. F. Scharff.

Science and Art Museum, Dublin, January 31.

I can assure Dr. Scharff that I took pains to read his full memoir before venturing to discuss it, as I think he should have recognised from the fact that the passage which I quoted from it did not occur in the abstract printed in Nature.

I readily acknowledge my inability to discuss the purely zoological questions which he has raised, and purposely avoided any attempt to do so. But as his methods have led him to conclusions as to the past geological conditions of the Irish Sea basin which are demonstrably at variance with the geological field-evidence in a crucial area, it seems desirable that a geological protest should be recorded against them.

If Dr. Scharff could be persuaded to reconsider his subject from a standpoint which should include both the zoological and the geological evidence, he might yet find some solution which would be satisfactory to the students of both sciences.

G. W. Lamplugh.

On Augury from Combat of Shell-fish.

In a foot-note to my letter on this subject (Nature, vol. lvi. p. 30, May 13, 1897), I remarked that the *Khchau* (a shell-fish), applied by the Cambodians to the divination of a war, is likely to belong to the family of Paludinidæ, taking into consideration the fact that the Japanese and the Chinese of former days used some species of viviparus (= Paludina) for the same purpose. Lately, while examining M. A. Parvie's article "Excursions dans le Cambodge, &c." in *Cochin-Chine Française; Excursions et Reconnaissances*, No. 9, p. 479, 1882, I have come across a passage giving confirmation to my view, The author, giving nomenclatures of the Cambodian molluscs, identifies the native *Kechau* (which is doubtless another French form of the spelling *Khchau*) with the Latin "Paludina"; whereas the allied genus Ampullaria has its Cambodian name "Tal."

Kumagusu Minakata.

January 31.

THE TOTAL ECLIPSE OF THE SUN.

Viziadurg, *Monday, January* 17.

The work is so incessant here from sunrise to midnight that I have not time to give anything like an adequate idea of our doings. I may say, however, that we have been here since last Saturday week, and everything is ready for the eclipse. We have now over 120 volunteers. Captain Chisholm-Batten has taken charge of the whole arrangement, and to me, an old eclipser, it is a beautiful thing to see the splendid drill which we have commenced in eclipse form, along all lines, to-day, going on to the sound of the bugle. The observers have been arranged into twenty-one parties as follows:—

Observing Parties.

	Instruments, &c.	Staff.
I.	6-inch prismatic camera	7
II.	9-inch prismatic camera	8
III.	Integrating spectroscope	3
IV.	Discs	18
V.	Sketches of corona, without discs ...	12
VI.	Colours of landscape	6
VII.	Shadow phenomena	8
VIII.	6-inch equatorial, with grating spectroscope	5
IX.	3¾-inch equatorial	3
X.	Hand spectroscopes, with slits	6
XI.	Prisms for observations of ring spectra ...	7
XII.	Timekeepers	3
XIII.	Contact observations	2
XIV.	Polariscope	2
XV.	Observations of temperature	13
XVI.	Observations of stars during totality ...	7
XVII.	Landscape cameras for shadow, &c. ...	7
XVIII.	Observations of shadow bands	3
XIX.	Kinematograph for eclipse	4
XX.	Kinematograph for shadow	2
XXI.	Coronograph	3
	Total	129

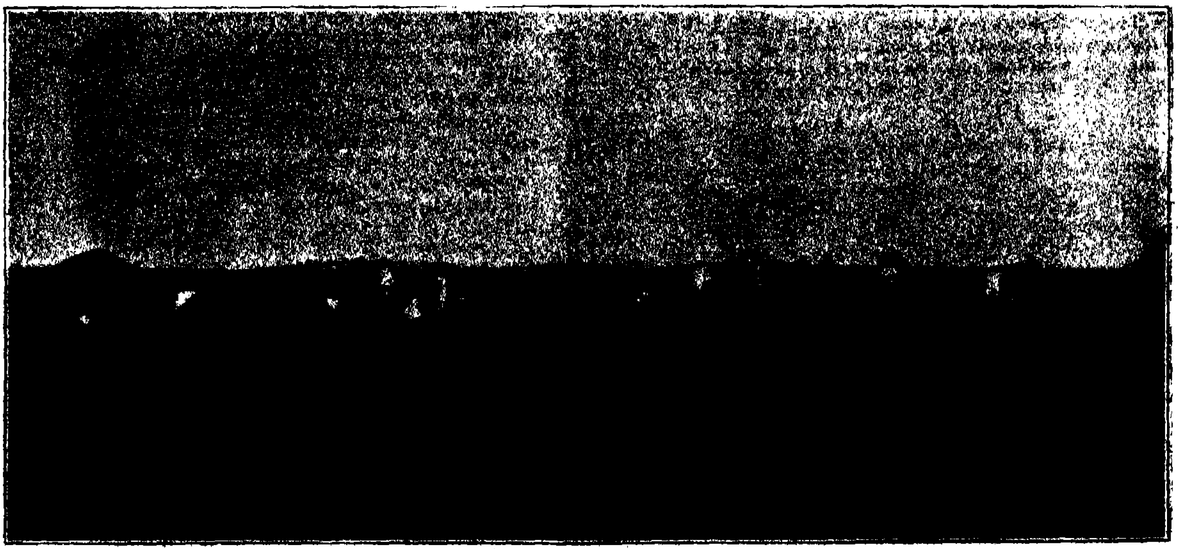

Fig. 1.—Camp, Saturday, January 8. Putting in concrete pillars.

Incessant instruction has been going on since the eclipse party joined the *Melpomene* at Colombo; but in this I have had quite a subordinate part to play, for the officers are past masters in many of the subjects which concern us. Our log of lectures, &c., between January 5 and 17, runs something like this :—

LECTURES, &C., JANUARY 5-17, 1898.

Wednesday, January 5.

General lecture.
Corona drawing.

Thursday, January 6.

Corona drawing, conducted by Mr. Fowler.

Saturday, January 8.

Lecture on spectra (forenoon).
Lecture on spectra (afternoon).
Colours of landscape, by Lieut. Dugmore, R.N.
Corona drawing.

Monday, January 10.

Lecture on spectra, by Lieut. Colbeck, R.N.

Tuesday, January 11.

Lecture on spectra, by Engineer Mountifield, R.N.
Colours of landscape, by Lieut. Dugmore, R.N.
Corona drawing, by Lieut. Dugmore, R N.

Wednesday, January 12.

Sketches of corona, with discs.

Thursday, January 13.

Colours of landscape, by Lieut. Dugmore, R.N.
Sketches of corona, with discs.

Rehearsal of drills for—

6" prismatic camera—9" prismatic camera—Description and sketches of corona, with discs—Timekeepers.

Friday, January 14.

Lecture on observations of stars during totality, by Lieut. Blackett, R.N.

Rehearsal of drills for—

6" prismatic camera—9" prismatic camera—Integrating telescope—Descriptions and sketches of corona, with discs—6" equatorial—3¾" equatorial—Timekeepers—Coronograph—Colours of landscape.

Saturday, January 15.

Drill for—

6" equatorial (morning), conducted by Prof. Pedler.

Rehearsal of drills for—

6" prismatic camera—9" prismatic camera—Integrating telescope—Descriptions and sketches of corona, with discs—6" equatorial—3¾" equatorial—Timekeepers—Coronograph—Colours of landscape.

Monday, January 17.

Drill for—

6" equatorial, conducted by Prof. Pedler.
Instruction on landscape cameras, by Messrs. Fowler and Turner.

Rehearsal at eclipse time of drills for—

6" prismatic camera—9" prismatic camera—Integrating telescope—6" equatorial—Timekeepers—Coronograph.

Rehearsal at 5 *p.m. of—*

6" prismatic camera—Integrating telescope—Timekeepers—Description and sketches of corona, with discs—3¾" equatorial—Coronograph—Colours of landscape—Kinematograph for shadow.

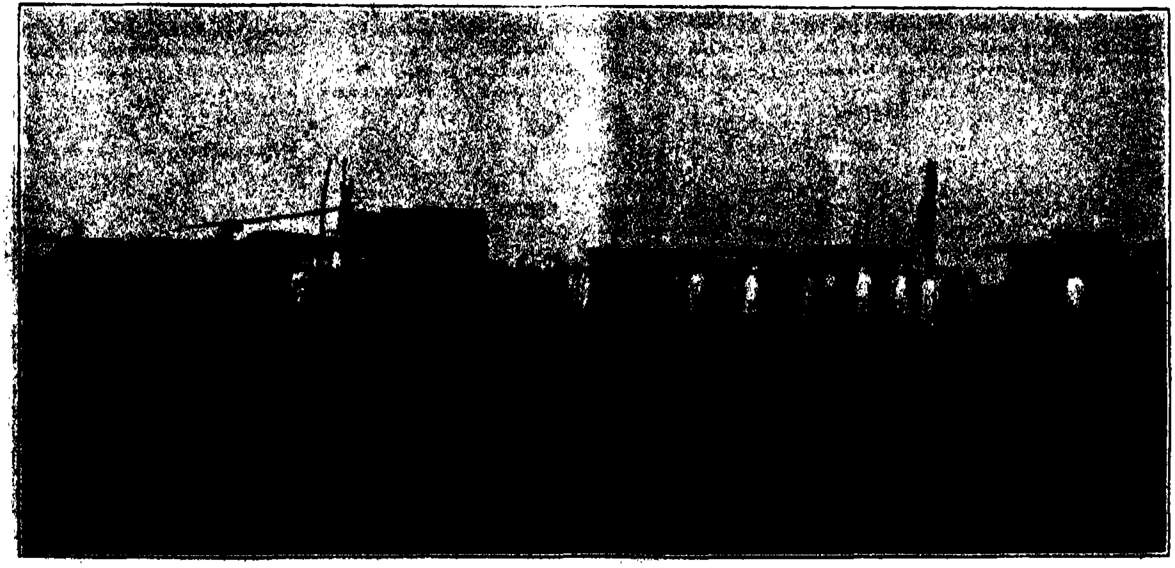

FIG. 2.—Camp, Monday, January 17. All instruments adjusted and drills commenced.

The climate here is delightful, and the weather has been up to the expected standard. To-day we have had a good deal of cloud after eclipse time; but our hopes are very high in spite of this, for it all disappeared before sundown, and to-night the zodiacal light has testified to the clearness of the air. From the first the arrangements of the Public Works Department have been admirable, and all the work has gone on like clockwork, till at last a large space in the Forts is now covered with structures of matting shielding the instruments, which leave nothing to be desired. Great precautions have also been taken against exposure to the sun, and as a result we are all perfectly well. It is impossible to say enough as to the help which the Captain of the *Melpomene* has given to the whole enterprise; he has anticipated all requirements down to the minutest detail. As at Kiö a signal station has been established, and everything the ship can lend, down to fire-buckets, is at our disposal in twenty minutes. The Collector of Ratnagiri, Mr. Bomanji, is also encamped here. At present he is our host, and any local assistance necessary is at once rendered; at first we had great difficulties, as the Bombay authorities imagined everything could be worked from the ship.

We have no news of the other parties, but Mr. Eliot, C.S.I., F.R.S., is expected to-morrow to take charge of the meteorological observations, and he doubtless will bring observers with him.

I enclose some photographs of the various instruments with their shelters. During the eclipse everything sunward will come down, and arrangements have been made so that everybody will have 40 seconds for a square look at the eclipse. The eclipse clock and timekeepers (we have a relay, one relieving the other at "65 seconds more") are working splendidly.

The new dropping-shutters, 16 × 6½, promise excellently; ten photographs of the spectrum can be taken in 10 seconds. A boat will be moored at the spot which we calculate the shadow will reach 5 seconds before totality, when the exposures begin; but we are not entirely dependent upon this, for the cusp will be watched, and again it has been calculated that this will extend through an arc of 45° at the same time (5 seconds) before totality. The arc will be watched to extinction in a 3⅜-inch telescope, and this will enable the general signal "go" to be given.

FIG. 3.—9-inch Prismatic Camera, showing arrangement and kind of shelter used.

Prof. Pedler has been here some days, and has got his 6-inch equatorial with grating spectroscope drill into perfect order. He begins 7 minutes before totality to repeat my Egyptian observations and studies certain special lines in the spectrum of the corona during totality. He has a comparison arc spectrum of iron, carbon, &c., photographed in the instrument before we came out.

NORMAN LOCKYER.

"A TRIP TO CANADA."

AMONG the more interesting and instructive results of the recent visit of the British Association to Canada, is the issue of a pamphlet entitled "A Trip to Canada" by a clergyman, who was one of the party.

The motives with which the journey was undertaken are given with a naïveté which commands respect. "The Jubilee of 1897," we are told, "naturally suggests the idea of a little foreign travel on one's own account. It is one thing to read about the Colonies; it is another to see them with one's own eyes. Where shall we go? There is a large choice. In these days there is a variety of Cook-like associations, which bid for one's patronage. This summer I was glad to take what came to hand. The British Association held its meeting last August in Toronto."

This is, indeed, a delightful picture. When the century was in the lusty hey-day of its youth and middle age, prelates and professors "gave and received hard knocks." Now, as the years roll on, science waits, hat in hand, on the country rector. His breakfast table is piled with the circulars of a "variety of Cook-like associations." As he cracks his egg he thinks of accompanying the geologists to Moscow and the Caucasus. A slice of cold ham recalls the Arctic Circle, the midnight sun and Thos. Cook. Then his vagrant fancy swerves to Grindelwald and Dr. Perowne. But with the first spoonful of marmalade he feels that the British Association and Toronto have secured the prize. He decides to patronise universal science and the British Empire.

The reasons for this decision were not less stupendous than the decision itself. Civilisation has travelled from east to west. "Let us," says the author, in a moment of pious aspiration, "let us follow in the track of Providence."

The idea of taking a "Cook-like" tour in "the track of Providence" strikes us as novel, and would, perhaps, have been thought to be profane had it emanated from Thos. Cook and Son themselves. Originating, as it does, with a clergyman, we can only bow the head and wonder at the varied manifestations of the religious instinct.

The alternative plans had been carefully considered, and the following sentences indicate the kind of information which had been collected. "The British Empire is composed of possessions in many parts of the globe. We hold India by military occupation; its 300 millions of people are put under our rule. Australia, New Zealand and Tasmania are in the Antipodes; Borneo, Singapore and the West Indies are in the tropics. Africa has various climes and races and interests. . . . Canada comes first among our possessions from a tourist point of view."

After this display of recondite knowledge, it will hardly be believed that one of the author's motives for taking a trip across the Dominion was that it improves one's geography; but this fact, reinforced by the arguments as to the "track of Providence" and the "tourist point of view" settled the matter, and to Canada our author went.

The journey once undertaken was as remarkable in its experiences as in its inception. "For the two first days [of the voyage]," says the traveller, "you feel more or less in a strange land." The feelings of the first two days are often so peculiar, that it is difficult to find words to describe them; but to feel "in a strange land" when you are really at sea is, we believe, a unique experience.

Arrived at the other side, "Quebec in electric light, as we gazed upon it, reminded me of Valetta between its two harbours, or even of Venice standing in its waters. It is commonly said to resemble Gibraltar." As we have always understood that there is a hill or cliff of some sort both at Gibraltar and Quebec, but that Venice is as flat as a pancake, we confess to being puzzled by this passage.

The first effect of Niagara on the traveller was exactly the opposite of that it ordinarily produces. "Niagara," he says, "makes one forget Lord Kelvin." The Horse Shoe Falls, we are told, "is a thing to see not once or twice, but to imbibe and sleep upon." The first of these phrases reminds us of the experiences of the young lady at Venice. "We have been out on the Grand Canal," she wrote, "drinking it all in. Life never felt so full before." We are not aware that there is any competitor for the originality of the idea of sleeping on the Horse Shoe Falls.

At Toronto our author's favourite subjects were geography and anthropology, but he "threw in a little geology and zoology." Prof. George Dawson will be sorry to hear that his address was dull; but Prof. Miall will be gratified by the following summary of his teaching: "He said you should not collect specimens and put them in bottles, but study their living habits."

We cannot follow the trip across the continent in detail.

Sometimes the author becomes didactic. "The old road [in the valley of the Frazer] is now disused, and the iron road has taken its place. . . . The two roads are a natural parable. The old road is like the way of the world, along which weary travellers toil and often lose hope. In the railway the voyageur (*sic*) travels safely and with rapidity. The cares of travel sit lightly upon him. He sleeps peacefully at night, and he enjoys the prospect by day. He looks on his journey's end with pleasure. He thanks . . . " But we refrain from giving the quotation which the author adds to this quaint specimen of moral reflection. The sleek tourist, carted about without any effort of his own except that of pulling his purse from his pocket, has never before, we suppose, been taken as the type of the "seekers after truth." The pioneer, hewing his way through the wilderness, careless if his road be rough or smooth is, we take it, much nearer to the conception which John Bunyan had formed of those who through the Slough of Despond, the Valley of the Shadow of Death, and the River itself, press forward to their goal.

One quotation more and we have done. We all remember the difficulty with which Martin Chuzzlewit escaped from the peremptory demand of Colonel Diver, "Let me ask you, sir, how do you like my country?"

Our author would have been equal to the occasion. "One is asked one's opinion about the country. That it is a great country is plain to all. A country of the size of Europe is not a small country. At present it is thinly populated. The Canadians think much of their country and everything in it. An enthusiastic young lady, whose home is in Ottawa, and who is on her way to a finishing school in London, said 'Don't you think the electric cars in Ottawa are better than anywhere else?' Of course they are, one cannot but reply, quite *boná-fide*. Would not she brighten an electric car, wherever she was?"

This is masterly. The judicial logic of the opening and the skilful retreat behind the young lady would have baffled Colonel Diver himself.

But enough of this. The note of the British Association is that it strives to bring the scientific expert into contact with the amateur, who is often a man from whom, on some special point, the expert may have much to learn. It is possible that some of those who are thus brought nominally within the scientific fold, care more for the cheap excursions and the "tourist point of view" than for the advancement of science. This is perhaps inevitable. At all events the Association has not chosen to attempt to sift the chaff from the grain, and the Canadians were willing to extend their generous hospitality not only to the group of well-known scientific workers who crossed the Atlantic, but to others whose only introduction was their Association ticket. As a member of the Association our author was everywhere kindly received, was carried across the continent half-price, and even enjoyed the pleasure (which he duly notes) of riding in electric trams for nothing. It might have been expected that he would have been grateful for the privileges which were extended to him in his presumed character of one anxious for the advancement of science. We have looked carefully through the pamphlet and find scarcely a single expression which gives evidence of any such sentiment. On the contrary he seems to think that the benefit was mutual. His last words are: "A trip to Canada is a pleasant experience. May I say that it gives pleasure to those whom one goes to see, as well as to the individual who makes the trip."

His scientific companions fare no better than his hosts. They are gracefully described as crossing the Atlantic "to disgorge their erudition well flavoured with salt." There is a contemptuous reference to "the smaller fry." A body which Sir John Evans, Lord Kelvin and Lord Lister were not ashamed to lead, is called "Cook-like." The author's whole attitude is that of a man who has paid his money, and has had no more than his rights.

We should not have dealt with this pamphlet at such length had it not been accompanied by a printed request for subscriptions for an object which many men of science would be glad to help. In his desire to benefit this object the author may give his work a wide circulation in this country and in Canada. We think it right, therefore, to draw attention to what otherwise might have been left unnoticed, in order to protest that this pamphlet must not be taken to represent the attitude of average members of the British Association.

None of them desired to imbibe Niagara, or are likely to forget Lord Kelvin. Amongst them there was the deepest feeling of gratitude for the hospitality they received; hospitality which the most distinguished acknowledged was more kindly and more lavish than they had any right either to expect or to desire.

THE HABITS OF ICE-SEALS.

THERE are four species of earless, or true seals inhabiting the boreal part of the North Atlantic and Arctic Oceans which may well be designated ice-seals, since they dwell for a considerable portion of the year either on the solid pack-ice or on ice-floes. These species are the Greenland or harp-seal (*Phoca grœnlandica*), often termed, on account of the conspicuous black markings on the yellowish-white ground-colour of the back, the saddle-back; the ringed seal (*P. hispida*); the large bearded seal, or square-flipper (*P. barbata*); and the crested, or hooded seal (*Cystophora cristata*), the males of which carry the peculiar dilatable sac on the nose from which the species derives its names. The first three of these are closely allied forms, but it is not a little remarkable that whenever the young of the first and second are born in a uniform yellowish-white coat, those of the third make their appearance in the world in a dark pélage; the white coat being not improbably shed *in utero*. It is commonly believed that the young of the fourth species are also white-coated, as are certainly those of the more southern grey seal (*Halichœrus grypus*). If a white coat serves as a protection to the new-born "pup" on the ice, it is difficult to see why this type of coloration should have been departed from in the case of one species. But the whole subject is one of great difficulty, as the white-coated young of the grey seal may often be seen in the Hebrides reposing on black rocks. All the four species in question agree in the circumstance that the young are produced during their sojourn on the ice; but in other respects very considerable differences are displayed in regard to habits.

In the first place, the Greenland and the crested seal are essentially migratory animals, the former associating in immense herds and the latter in smaller parties, whereas the bearded seal, which is considerably the largest of the three, only makes a slight movement to the south when compelled by the increase of the winter pack-ice, and is a comparatively solitary creature. But these are by no means the only points of difference in this respect. The Greenland seal visits the country from which it takes its name twice annually, namely in the autumn and the spring; and breeds chiefly on the coasts of Jan-Mayen and Newfoundland, the young being produced in the latter district at the beginning of March, but in the former some weeks later. That some of these seals which migrate from Greenland travel westwards to Jan-Mayen is most probable, but where the remainder pass their time while away from their native land, is not yet ascertained with certainty. The southern migration of these seals on the Atlantic coast of America, which commences when the frost sets in, is described as a wonderful sight; at first small advance parties pass down, and these are followed by the main body, which includes thousands of individuals, and takes about a couple of days in passing a given point. Although during their migration hugging the coasts, the Greenland seals during the breeding-season frequent the heavy floe-ice, at least in East Greenland, which is not liable to break up, and therefore affords them a safe habitation. As they have no difficulty in obtaining access to the water, in this district, at any rate, they do not make breathing-holes; and it has been commonly supposed that this is their invariable habit, but in a little pamphlet recently issued by Commander Robinson,[1] entitled "Ice-riding Pinnipeds," it is stated that when on solid thin ice such holes are made. In disposition this seal is mild and gentle; and it is a well-ascertained fact that the young are born in the white coat, the British Museum possessing a stuffed example in this state. From its numerical abundance it is commercially one of the most valuable of the true seals.

As regards the bearded seal, this, as already mentioned, is a comparatively rare and solitary species, fond of reposing on floating ice in the open sea, and moving southwards only when compelled by the extension of the pack-ice. It is apparently one of the species which does not make a breathing-hole, as it does not frequent large extents of ice; and it may generally be recognised at a distance by its habit of performing a somersault when diving into the water. In the pamphlet already referred to the suggestion is made that a certain number of the young of this species are infected by the migratory instinct of the young Greenland seals, and wander south with them. In addition to the testimony of sealers, a specimen in the Natural History Museum conclusively proves that the young "square-flipper" is born in the dark coat.

The ringed seal, which is common to the North Atlantic and Pacific, is a non-migratory species, whose favourite haunts are retired fjords and bays, in which it remains during the time they are tightly packed with ice. When, however, the ice breaks up, the "floe-rats," as they are called by the sealers, retire to the ice-floes, upon which the young are born in March and April. This species always form an "atluk," or breathing-hole in the ice, which is in the form of an oblique passage, through which the surface of the ice can easily be reached from below. The hole appears to be made while the ice is forming; but accurate accounts of the *modus operandi* are still required. In the above-mentioned pamphlet it is stated that the animal works on the ice with its front claws, revolving round this pivot with its body; but it is somewhat difficult to realise how such a method can be effectual, and, *primâ facie*, it would seem more probable that the passage is made while the ice is sufficiently thin to break with the weight of the seal, and kept open by constant use. The breathing-hole affords an easy method of capturing the seals which use it, and the great reduction in the number of these seals is largely due to this method of hunting.

As it differs much in external form from other ice-seals, so the crested seal has several peculiarities in habits. Unlike the others, it is a bad-tempered animal, living, except when driven to associate more closely by an unusual scarcity of ice, in small parties scattered over a wide extent of ice, always preferring the outside of the pack, or drift ice to the neighbourhood of land, and seldom frequenting either the coasts or isolated rocks. On the American side they are chiefly to be met with near the eastern edge of the main ice-pack, where there are numerous patches of open water, and consequently abundant room for fishing. Ordinarily small parties of from three to five individuals are scattered over the broken rough ice, at distances of from thirty to fifty yards apart. The easy access to water thus afforded obviates in general the necessity of making breathing-holes. They are stated to resemble fur-seals in being polygamous; and the males certainly engage in combats for the possession of the females, during which they utter loud cries which may be heard for miles. In winter these seals travel south, but they do not make the two annual journeys characteristic of the saddle-backs in Greenland. In European seas the crested seal has become comparatively rare, although on the American side, where its favourite haunts are Labrador and Newfoundland, it is still so abundant that many thousands are at times taken by a single vessel. March is the breeding-time, and at this season the young are produced on the ice far away from land. All previous writers with which we are acquainted state that the young are born in the white coat, which is not exchanged for the grey till the lapse of about twelve months. But Commander Robinson is positive that this is incorrect, and that the grey coat is assumed previous to birth. Unfortunately there are no specimens in the British Museum available for deciding this disputed point; but it is earnestly to be hoped that such may be supplied before long. In the meantime it may be suggested that the discrepancy has arisen from the young of one species having been mistaken for that of another, although it is at the same time difficult to see how this can have been the case with a seal so peculiar in appearance, and dwelling so much apart as does the present.

---

[1] I am informed by the author that, owing to certain errors, all available copies of this work have been cancelled.

The above are but a few of the leading features in the habits of the northern ice-seals, to describe which in detail would require a small volume. Among the points which require special elucidation are what becomes of the great bulk of the harp-seals between their visits to Greenland in May and September, the mode in which seals make their breathing-holes, and the colour of the newly-born crested seal. R. L.

MAGNETIC AND PENDULUM OBSERVATIONS.[1]

It may be remembered that Lieutenant Peary, before starting on his sixth expedition to Greenland in 1896, offered transport on his steamer to two parties of scientific men, and that the opportunity was very properly accepted. The parties—which were under the direction respectively of Prof. A. E. Burton, of the Massachusetts Institute of Technology, and Prof. R. S. Tarr, of Cornell University—consisted each of six members, and were entirely independent in organisation and equipment of the main body of the expedition. The researches of the Boston party consist of observations in terrestrial physics, including glacier phenomena, and studies of Eskimo life, and their reports are now coming to hand. The report of Mr. G. R. Putnam, of the United States Coast and Geodetic Survey, who undertook the magnetic and pendulum observations, is now before us.

Early in July Mr. Putnam left Boston with a complete outfit of magnetic, pendulum, and astronomical instruments, and arrived at Halifax, Nova Scotia, two days later. Here he found time to make magnetic determinations at the Naval Dockyard, at which station the declination observations cover a period of nearly three centuries. Reaching Sydney, Cape Breton, the starting point of the expedition proper, six days elapsed before the departure of the *Hope*, Lieutenant Peary's steamer, and in this time all the instruments were set up and used. The voyage along the Labrador coast was only interrupted by a few hours' stop at Turnavik, where magnetic observations were made. Passing up the Hudson Straits, Mr. Putnam spent two days at Ashe Inlet, but here a gale on the second night unfortunately interfered with the full success of his work. The *Hope* then turned eastward, and on August 1 the coast of Greenland was sighted. Magnetic observations only were made at Godhavn, and Umanak was reached a day or two after. Here Mr. Putnam's party landed and settled down for a month, while the *Hope* continued her northern voyage. The required observations having been completed, the whole party indulged in exploring trips, but on these excursions they could not well take the magnetic instruments. On the return of Lieutenant Peary, the homeward journey began. After the magnetic observations at Godhavn had been repeated, the ship anchored at Niantilik, in Cumberland Sound, where observations were again attempted, but here the value of the pendulum observations was lessened, because unfavourable weather did not allow the necessary time-observations. Sydney was again reached September 26, and here a few observations were taken, prior to the instruments being shipped to Washington, where they were tested and found to be unaffected by their long journey of 5000 miles.

The magnetic outfit, comprising a dip circle of the ordinary Kew pattern and a magnetometer, was lent by the Coast and Geodetic Survey. In the case of the latter instrument, the magnet consisted of a hollow octagonal prism of steel, held in a stirrup with a long arm to which the two silk fibres were attached. By this arrangement the magnet remained sensibly horizontal at ordinary latitudes, but a copper balancing ring was sometimes used at the most northerly stations. The formula used for computing the moment of inertia of this ring (p. 74) is incorrect, and the term $\frac{1}{3}(x_2^2+x_2x_1+x_1^2)$ should be replaced by $\frac{1}{4}(x_2+x_1)^2$, although the numerical correction happens to be insensible. For determining the azimuth by the sun, the magnet box is removed from the base and circle, and the latter is then used with a separate theodolite.

Mr. Putnam's results in this part of his work are both valuable and interesting. Further evidence has been obtained of the violence of magnetic disturbances in polar regions, although far greater disturbances have been recorded. Thus the range in a day observed at Niantilik exceeded 4½ degrees, a change of over 3 degrees being noticed in twenty minutes. A comparison with the contemporary record at Washington reveals, it is true, that an unusual magnetic storm visited this city, but its severity as measured by the range of declination was fifteen times less than that at the northern station. With the exception of Niantilik, earlier information is available with regard to all the stations visited by Mr. Putnam; and although only Halifax and Godhavn possess satisfactory records extending over the last three-quarters of a century, the general tendency in the change of the magnetic elements seems to be clearly indicated. At present it appears that at all these points "the westerly declination is diminishing, the northerly dip is diminishing, the horizontal force is increasing, and the total force is diminishing."

The apparatus used for determining the relative force of gravity, comprised a set of three half-second pendulums, one sidereal and two mean time chronometers, and a meridian telescope. The pendulums were swung in an air-tight case, in which the pressure was reduced to about 6 cm. by means of an air-pump. All the chronometers were provided with electrical break circuit attachments, and were thus capable of the instantaneous raising of a shutter by an electrical mechanism and the momentary illumination of a slit every second or two seconds. By this means the reflections of a flash in two mirrors, one attached to the fixed knife edge, and the other to the head of the pendulum, could be observed in a telescope. The period of the pendulum was then deduced from the observed coincidences. At the southern stations coincidences were observed with sidereal seconds, but nearer the pole, with mean time seconds, on account of the decrease in the period of the pendulum. Whenever the plan could be carried out each pendulum was swung for a period of eight hours, both in reversed and direct positions, and star observations were made at the beginning and end of the forty-eight hours. The following table summarises the principal results (p. 103):—

---

[1] "The Scientific Work of the Boston Party on the Sixth Peary Expedition to Greenland. Report A."

Station.	Latitude N.	Longitude W. of Greenwich.	g_1, reduced to sea level.	g_0, theoretical value.	$g_1 - g_0$.
	° ′	° ′	cm.	cm.	cm.
Washington ...	38 53	77 1	980·101	980·087	+ 0·014
Sydney (Cape Breton) ...	46 9	60 12	980·722	980·732	− 0·010
Ashe Inlet ...	62 33	70 35	982·109	982·104	+ 0·005
Umanak ...	70 40	52 8	982·594	982·632	− 0·038
Niantilik ...	64 53	66 20	982·275	982·271	+ 0·004

The theoretical value is that given by the assumed formula,

$$g_0 = 978·066\,(1 + 0·005243 \sin^2 \text{latitude}),$$

and g_1 is obtained by using Bouguer's formula.

It would not be easy to over-estimate the value of these accurate determinations of gravity, for they help to fill a very serious gap in the series of observations which have been made in various parts of the world. Prof. Helmert's recent report to the International Geodetic Association has shown that no pendulum observations had been obtained in the region visited by Mr. Putnam, and it is in the polar regions that data as to the variations of gravity are of the greatest importance and, therefore, most urgently required. Mr. Putnam concludes his report with some historical notes on the development of apparatus and the progress of research, which are very interesting. It is hardly correct, however, to say that the law $t = \pi\sqrt{\frac{l}{g}}$ applies even to the ideal simple pendulum (p. 110). These notes contain a good account of the controversy which has arisen about the appropriateness of the second term in Bouguer's formula for the reduction of g to sea level: $dg = \frac{2gH}{r}\left(1 - \frac{3\delta}{4\Delta}\right)$, where δ is density of matter lying above sea level, and Δ is the mean density of the earth. The value of pendulum observations as affording indications of surface density is insisted upon, and a practical application of the method is suggested. It is to be hoped that Mr. Putnam will see his project realised, by which the relative proportions of ice and rock in the great Greenland elevation may be determined by pendulum experiments.

RAINFALL OF THE UNITED STATES.

UNDER this title the Weather Bureau of the Department of Agriculture has published a bulletin containing a discussion of the observations obtained from the longest and most trustworthy rainfall registers in the United States, accompanied by annual, seasonal, and other charts. In addition to the usual tables of the mean monthly and annual precipitation, arranged according to geographical distribution, an important departure has been made by separately discussing the rainfall of the crop-growing season; for, as the author remarks, however valuable a knowledge of the water supply throughout the year may be, information as to the amount of rainfall available for agricultural purposes is possibly of greater consequence.

Another departure from the ordinary treatment of the subject is the discussion of the monthly distribution by districts and types according to natural boundaries. The conditions favourable for rainfall are chiefly (1) nearness to the ocean, (2) proximity to the track of storms, and (3) the position of mountain ranges. The rainfall of the North Pacific coast is quoted as an example of the combined effect of all three conditions, the distinguishing characteristic of this type being a wet season from October to March, and a practically rainless summer, except in Northern California and parts of Oregon and Washington. About half of the yearly fall occurs between December and February. The rainfall is discussed under twelve such types; we are unable to refer specially to each of these, but the chart of mean annual precipitation shows that there is a narrow belt on the north-west coast, extending from Cape Flattery on the north to midway of the Oregon coast on the south, and some distance inland, where the annual amount exceeds 50 and at some points 100 inches. Eastward and southward the annual fall diminishes, reaching a minimum on the lowlands and valleys between the Coast Range on the west and the Sierra Nevada and the Cascade Ranges on the east, where the amount in some cases does not exceed 10 inches, but in years of plentiful rainfall as much as 20 inches may fall in the best-watered parts. At Terrace (Utah), a station on the Central Pacific Railroad, the mean annual fall is only 4·3 inches, and in the driest year was as low as 0·7 inch. To the eastward of the Rocky Mountains the annual fall is from 10 to 18 inches, and increases slowly to 60 inches on the Florida and Gulf coasts, and from 40 to 50 inches in the Eastern States. There is, however, a gradual decline both from the Atlantic coast westward and from the Gulf coast northward. In considering the various rainfall values in this discussion allowance must be made for the position of the gauges which are generally exposed on roofs, owing to the stations being mostly in towns. It is well known that the amount caught in the gauge decreases with altitude above the ground, and it is estimated that the loss from this cause in the values quoted by the Weather Bureau is from 5 to 10 per cent. of the total annual fall. With regard to the important subject of excessive rainfall, down to the year 1888 only one self-recording gauge was in use at the Signal Service stations; five others were added in 1889, and the publication in the *Monthly Weather Review* of the maximum falls in five and ten minutes, and also in one hour, were begun. In August 1890 a cloud-burst passed over Palmetto (Nevada), when a gauge that was not exposed to the full intensity of the storm caught 8·8 inches of water in an hour, and in August 1891, 11½ inches were measured within an hour at Campo (California). The great majority of excessive rains are said to occur east of longitude 105° W., and principally in the summer months, in connection with afternoon thunderstorms; they occasionally take place in the track of West India hurricanes, and are more abundant on the Gulf and South Atlantic coasts than at inland places. The maximum rates of rainfall per hour, estimated from periods of five minutes, at the Weather Bureau Stations which possess self-registering gauges, were 9 inches at Bismarck (N. Dakota); 8·4 inches at St. Paul (Wisconsin), and 8·2 inches at New Orleans.

This valuable memoir has been prepared by Mr. A. J. Henry, under the direction of Prof. Willis L. Moore, the Chief of the Weather Bureau.

NOTES.

THE German Emperor, as King of Prussia, has conferred upon Dr. John Murray, Director of the Scottish Marine Station, and formerly of the *Challenger* expedition, the rare distinction of knighthood in the Order *Pour le Mérite* founded by Frederick the Great. This is generally allowed to be the highest honour which a man of science can receive, and is limited to thirty German and twenty-five foreign knights. Lord Kelvin, Lord Lister, and Sir G. G. Stokes are the only other British men of science now alive who have received the Order. Dr. Murray has also been elected a Foreign Member of the Imperial Russian Academy of Sciences.

THE Committee appointed by the American Society of Naturalists to inquire into the practicability and feasibility of the exploration of the Antarctic continent, report that an expenditure of from forty thousand to fifty thousand dollars would suffice for an independent scientific expedition. The Committee suggests that if this fund could not be raised by public subscription, a number of scientific societies and institutions of general learning, should contribute the amount required, each sending representatives to the expedition in proportion to the sums subscribed.

We are glad to hear that the *Zoological Society of London* has contributed 100*l.* towards the expenses of the International Congress of Zoology; and we hope to hear that other natural history societies have followed this excellent example.

Sir Dyce Duckworth has been appointed to deliver the Harveian Oration before the Royal College of Physicians of London for 1898. Dr. G. V. Poore has been nominated Milroy Lecturer for 1899.

The Council of the Institution of Civil Engineers have resolved that the "Engineering Conference," inaugurated in 1897, is to be biennial, and that, accordingly, the next meeting will be held in London in the spring of 1899.

A large and representative Royal Commission has been appointed to advise as to the best means by which the products of British industry, agriculture, and the fine arts may be procured and sent to the International Exhibition to be held at Paris in the year 1900. Among the Commissioners, which include the Prince of Wales and the Duke of York, are the following representatives of science and the arts, in alphabetical order:—Sir F. A. Abel, Sir George Birdwood, Major-General Sir Owen Tudor Burne, Sir G. H. Chubb, Major-General Sir John Donnelly, Lord Kelvin, Sir James Kitson, Sir Trevor Lawrence, Lord Lister, Sir John Lubbock, Sir Clements Markham, Mr. W. H. Preece, Mr. E. Windsor Richards, Earl Spencer, Mr. W. T. Thiselton-Dyer, Sir E. Maunde Thompson, and Sir W. H. White.

M. Franchet has been elected President of the Botanical Society of France for the current year; MM. Zeiller, Boudier, Clos, and Roze Vice-Presidents.

Prof. O. Mattirolo, of Bologna, has been appointed Professor of Botany and Director of the Museum and Botanical Garden at Florence; Prof. F. Morini, of Messina, takes his place at Bologna.

On December 18, 1897, a hall was opened at Bologna for the reception of the herbaria, preparations, and sections of the botanist Aldrovandi. It has been erected at the cost of the city and province.

The part of *Malpighia* comprising fascs. 9 and 10 for the year 1897, edited by Prof. O. Penzig, contains a view of the very handsome monument erected to the memory of Malpighi at Crevalcore.

The post of Government botanist to Victoria, vacant by the death of Baron Ferdinand v. Müller, has been conferred on Mr. J. G. Luchman.

The death is announced of Dr. Waldemar v. Schroeder, professor of pharmacology in the University of Heidelberg, and author of a number of treatises on physiological chemistry.

We learn from *Science* that the Bruce gold medal of the Astronomical Society of the Pacific has been awarded to Prof. Simon Newcomb, for his distinguished services to astronomy.

The American Academy of Arts and Sciences has elected M. Elias Metschnikoff, of Paris, Foreign Honorary Member in the Section of Zoology and Physiology.

The twenty-sixth general meeting of the Federated Institution of Mining Engineers will be held at Newcastle-upon-Tyne on February 22 and 23.

At the annual general meeting of the Royal Horticultural Society, held on Tuesday, the Council announced that they had appointed the Rev. George Henslow to be professor of botany to the Society, and that Prof. Henslow had kindly undertaken to give addresses at a number of the 1898 meetings, drawing attention to interesting points connected with some of the plants, &c., exhibited. The Council believe that these "demonstrations" will be greatly appreciated by the Fellows of the Society.

At the general monthly meeting of the members of the Royal Institution, on Monday, the special thanks of the members were returned to Mrs. Tyndall for her liberal donation of 1000*l.*, presented in the name of the late Prof. Tyndall, for the promotion of science Thanks were also returned to Sir Frederick Abel, Sir Andrew Noble and Prof. Dewar for donations to the fund for the promotion of experimental research at low temperatures. It was announced that the centenary of the Royal Institution would be celebrated next year.

The meeting of the Manufacturers' Association of America at New York, on January 25-27, was the most notable gathering of the masters of industry ever held in America, or probably in the world. It was estimated that the 966 persons who attended the closing banquet represented industries which produce 9,000,000,000 dollars of manufactures annually. In the meetings of the Association prior to the banquet the subject of the metric system was presented by the committee, together with a resolution strongly favouring it; which resolution met with support from many of the most influential members of the Association, but was opposed by the chairman of the committee on the grounds of the expense of making new gauges and tools in changing from the present standard. The final result was that the resolution was not carried.

Further particulars of Prof. O. C. Marsh's valuable gift to Yale University (see p. 322) are given in the *Yale Alumni Weekly*. From a scientific point of view, the value of the collections now presented to Yale is beyond price, each one containing many specimens that can never be duplicated, and are already of historical interest in the annals of science. Among the prominent features of one of these collections, that of extinct Vertebrates, may be mentioned (1) the series of fossils illustrating the genealogy of the horse, as made out by Prof. Marsh, and accepted by Huxley, who used it as the basis of his New York lectures; (2) the birds with teeth, nearly two hundred individuals, described in Prof. Marsh's well-known monograph "Odontornithes"; (3) the gigantic Dinocerata, several hundreds in number, Eocene mammals described in his monograph on this group; (4) the Brontotheridæ, huge Miocene mammals, some two hundred in number; (5) Pterodactyles, or flying dragons, over six hundred in number; (6) the Mosasaurs, or Cretaceous sea-serpents, represented by more than fifteen hundred individuals; (7) a large number of Dinosaurian reptiles, some of gigantic size. Besides these are various other groups of mammals, birds, and reptiles, most of them including unique specimens.

In referring to the priceless collections which have now become the property of Yale University, by Prof. Marsh's generosity, the *Alumni Weekly* remarks that Prof. Marsh is a Yale graduate of the Class of 1860. He is a nephew of the late George Peabody, and thus he secured the donation that gave Yale the present Peabody Museum, as well as a reserve building fund that then seemed adequate for future additions. After obtaining this great gift for Yale, Prof. Marsh served his *alma mater* faithfully, without salary, for thirty years, as professor of palæontology, refusing all offers to go elsewhere. Besides bringing together with untiring zeal these vast scientific collections now presented to the University, Prof. Marsh has found time to describe many of the important specimens new to science, and make them known to the world in more than two hundred and fifty publications.

WE have been requested to announce that it is proposed to raise, by international subscription, a memorial fund to the late Prof. Edmund Drechsel, the well-known physiological chemist, whose recent death at Naples, on September 22, 1897, has been a great loss to science. Prof. Drechsel has left a widow and two young sons in very poor circumstances. It is hoped that sufficient money will be raised to contribute materially to the support and education of these boys, as well as to provide a modest memorial to Drechsel in the place where he is buried. Any contribution to this object may be sent direct to Prof. Kronecker, Physiologisches Institut, Bern; or to Mr. Ernest H. Starling, 8 Park-square, London, N.W., who will forward any subscriptions received to Prof. Kronecker. This appeal has been circulated among the members of the Physiological Society; but Drechsel was even more a chemist than a physiologist, and many English chemists, as well as other scientific men, may be glad to contribute in some way to the memorial which is being raised on behalf of his widow and children.

WITH reference to the recrudescence of epidemic influenza the *British Medical Journal* says:—Influenza has further increased in London during the past week, and medical practitioners in all parts of the town are finding their hands very full. The epidemic seems to be very prevalent also in some of the home counties, especially in Kent and Surrey, and it prevails also in Devonshire and Cornwall. The epidemic now prevalent, in some districts at least, differs in its character from those from which we have suffered in previous years. It has long been recognised that the disease may present at least three distinct types, according to whether it attacks most severely the respiratory, the nervous, or the digestive systems. In the earlier epidemics in recent years the majority of cases belonged to the first type, and many deaths were caused by bronchitis and pneumonia. Later, the prevalent type was the nervous, and men were left in a condition of mental and physical depression which for many months greatly limited their activities, and in too many cases helped to fill the asylums. The present epidemic is remarkable for the very large proportion of cases which show symptoms of profound disturbance of the digestive system.

IT is surprising that in a subject like mathematics, where any student may easily rediscover known theorems for himself, so few journals exist devoted to the interchange of notes and queries. We are glad to see that *L'Intermédiaire des Mathématiciens*, which exactly fulfils this object, has now entered on its fifth year of publication. The editors, Dr. C. A. Laisant and M. Émile Lemoine, justly take pride to themselves in recording that the recent Mathematical Congress in Zürich owed its origination partly to correspondence in their columns.

A NOTE by Commander C. H. Davis in *Terrestrial Magnetism*, calls attention to the serious effects of electric car disturbances at the magnetic observatory of the United States Naval Observatory, which is situated on Georgetown Heights, in the suburbs of Washington. The disturbances seem to have most affected the vertical force, but the horizontal force and declination were also disturbed. Experiments conducted at the magnetic observatory of Toronto, which is still in a worse predicament than this observatory, show that magnetic instruments must be removed to a distance of at least two miles before the disturbances of an electric railway cease to be apparent. Observations at Toronto have been discontinued. As Commander Davis remarks, it thus appears that the use of powerful electric currents for commercial purposes has destroyed the usefulness of the only two magnetic observatories on the North American continent.

THE *Aeronautical Journal*, which now enters on its second year of publication, bids fair to be a current record of all experiments on aeronautical matters as well as of devices, both practicable and impracticable, for navigating the air. Among the features of the current number are an account of Mr. Chanute's American experiments, and a translation of a paper, by Captain Moedebeck, on the German aluminium balloon which was experimented with on November 3 of last year, but was wrecked through becoming unmanageable. That never-failing subject of controversy, the "soaring bird," is again brought forward, this time in a lengthy disquisition by Mr. G. L. O. Davidson. Mr. P. Spencer describes Mr. Pollock's balloon trip of October 12, 1897, across the Channel; and Mr. A. Lawrence Rotch, of the Blue Hill Observatory, contributes a note on "The Highest Kite Ascent." A glance at the list of patents applied for, and actually granted, will show that the "dark ages" of science have not yet entirely disappeared, so far as aeronautics is concerned.

A SMALL pamphlet, entitled "Natural Colour Photographs," has been received from the Natural Colour Photography Company, Ltd., Dublin; and though Prof. Joly's name is not mentioned in it, the process described is evidently the one we owe to his ingenuity. This process, it will be remembered, consists in using two screens: one—the "taking" screen—lined in orange, yellowish-green and blue; and the other—the "viewing" screen—lined in red, green and violet. The pamphlet just received is taken up with directions for using these screens, the former of which is employed to obtain the negative, while the latter—when superimposed upon the positive finally obtained—reproduces the colours of the original object, which appears as a transparent photographic image in the natural colours. Many photographers will be glad to know where to procure these screens, and how to obtain the best results with them.

AT the meeting of the Academy of Sciences at Vienna, on January 20, Dr. J. Hann communicated a treatise on the theory of the daily oscillation of the barometer. The chief object of the discussion is the investigation of that portion of the regular oscillation of the barometric pressure which occurs once in an entire day. This period is most subject to disturbances of locality and time because all meteorological phenomena have a whole-day period. With the view of eliminating all disturbing influences as much as possible, the author deals with the hourly observations made at sea, and on islands far from continents. Near the equator the extremes of the whole-day period occur near 5h. 30m. a.m. (the maximum) and 5h. 30m. p.m. (the minimum), which are not very different from the average conditions on land, the epochs being retarded with increase of latitude. The amplitude of the whole-day oscillation at the equator is nearly a third of that of the double daily variation. The amplitudes of the daily wave have two principal maxima at the time of the equinoxes, and a principal minimum in June and July, at the time of aphelion; while in December and January, at the time of perihelion, the amplitude is much greater. The author also investigates, for a number of stations, the modifications to which the normal whole-day wave of barometic pressure is subject, owing to the daily periodic transfer of masses of air from land to sea, and the reverse, as well as at mountain stations.

THE Hong Kong Observatory seems to have been originally founded for the purpose of issuing storm warnings and protecting commerce against the destructive typhoons which visit those parts. Looked at from that point of view the Observatory seems to have fulfilled its original object. The Report for 1896, just received, gives a full account of the work carried on, and particularly analyses the relative success that has attended the weather and storm predictions issued. Adopting the general method of taking the sum of total and partial successes as a measure of success, and similarly with the failures, we learn that 97 per cent. of the weather forecasts have been justified. With regard to the success in predicting the approach of a typhoon, the percentage is nearly as good, if we leave out of account a peculiar storm, prevalent in the winter, called a "Norther," and of which it is impossible to publish any forecast till information is available from the interior of China and the northern ports. For instance, there appears to be no telegraphic communication between the Observatory and either Hankow or Cheefoo, so that all information from a particular direction is wanting, which, if it could be obtained, would add materially to the safety of the shipping and commerce. But notwithstanding these disadvantageous circumstances, the percentage of success is 75 for all gales, and leaving out those for whose successful prediction northern information is necessary, the percentage is as high as 83. Among the original inquiries prosecuted at the Observatory is one on anemometer records at various altitudes. Two Robinson anemometers of identical construction are mounted at 150 feet and 1834 feet above mean sea-level. The lower is at the Observatory on the Chinese mainland, the higher on the island of Hong Kong. The result is to show the ratio between the force of the wind at the two stations for each hour of the day throughout the year. In the summer, when the wind is generally southerly, the proportionate velocity is greater than in winter, when the wind is easterly. Similarly at midnight, and the morning hours, the difference of velocity is greater than at noon, and the hours immediately after.

THE *Pharmaceutical Journal* is doing its best to encourage the use of the metric system by pharmacists in their daily business. Recent legislation has made the use of the system legal in British commerce, but, as our contemporary points out, the mischief of a permissive system is that what is permitted is often, as a matter of convenience, ignored; and there is little doubt that the mere permission to use metric weights and measures in trade will prove futile in encouraging the general adoption of the system. The suggestion is offered, therefore, that pharmacists should neglect no opportunity of familiarising themselves, and those with whom they come in contact in the course of their business, with the more rational weights and measures that are now legal, the more especially as they appear destined, sooner or later, to supplant the older weights and measures entirely. With the view of encouraging and assisting the reform indicated, it is proposed in future to give all quantities in the pages of the *Pharmaceutical Journal* in accordance with the metric system, and the change will be effected in its entirety at as earlier a period as may prove convenient. After the new Pharmacopœia is published, there will be no excuse for British pharmacists to plead unfamiliarity with the metric system.

AMONG the more valuable incidental results of the Canadian meeting of the British Association must be reckoned the advances in our knowledge of the surface life of the North Atlantic, made by members of the Association during their outward and homeward voyages. We have referred in earlier numbers to the collections of plankton made by Prof. Herdman along the Canadian transatlantic route, and by Mr. Garstang along the Canadian and American routes. Prof. Herdman's account of his work is the first to appear, and has been published as a memoir in the *Transactions* of the Liverpool Biological Society (vol. xii.), under the joint authorship of Prof. Herdman, Mr. J. C. Thompson, and Mr. Andrew Scott. The memoir reveals a remarkably wide distribution for the majority of the forms enumerated. Four new species of Copepoda are described, three of them from the St. Lawrence and one from Puget Sound on the Pacific Coast. The discovery of these forms by English visitors should encourage Canadian naturalists to take up this promising field of research for themselves.

IN order to obtain positive data as to the results of the serum treatment of diphtheria in Russia, the two St. Petersburg societies, of Children's Physicians and of Russian Physicians, nominated a special committee which studied all that had hitherto been printed in Russia on the subject, and entered into correspondence with the doctors who had used serum in their practice. An elaborate report of the committee was read, on December 24 last, by Dr. Rauchfuss before a meeting of the Society of Russian Physicians. In 44,631 registered diphtheria cases in which serum was used, the mortality was only 14·6 per cent., while in 6507 cases where no serum was used, the mortality was more than double, *i.e.* 34 per cent. By a careful analysis of data taken from 51 provinces of Russia, Dr. Rauchfuss shows that in each province separately the serum treatment had the effect of at once notably reducing the mortality, even in the midst of severe epidemics. He does not deny that medical help is now applied for in a number of lighter cases, in which no doctor would have been called for a few years ago; but the marked difference between the mortality in the cases which were treated with serum and those which were not, cannot be explained in this way, while the confidence of the population, including the peasants, in the new treatment is also a testimony in favour of it. Eleven laboratories situated in different parts of Russia are now preparing diphtheria serum.

IT is now recognised that properly-organised and equipped museums are valuable factors in education, and render good service in directing and stimulating scientific work. Unfortunately, owing to general lack of means, and a staff the members of which have not received sufficient training, provincial museums are often of no service to education or to science. In *Natural Science* (December 1897), Mr. Herbert Bolton refers to these museums, and points out that hardly any two can be said to work upon a common plan, whilst most develop and exist rather as the sport of circumstances than as the outcome of definite purpose and design. What is badly wanted is the creation of an annual museums' grant by Government in aid of provincial museums of University Colleges, and of large cities possessing good collections and a trained staff, the sum allotted to each being determined by considerations similar to those which guide the application of the present University Colleges' grant. Upon the strength of such a grant the Government could charge each museum with a definite scope of work and the attainment and retention of a certain standard of excellence. It is also suggested that other museums might be subsidised through the agency of Council Councils, upon certificates of efficiency and progress received annually from an accredited visitor, who might be an official of the Government or of one of the first-class museums. Mr. Bolton's scheme of classification of museums, and of the work these institutions might do, should assist in directing attention to an important subject.

M. J. DENIKER (*Bulletins de la Société d'Anthropologie de Paris*, 1897, fascicules 3 and 4), in a paper of considerable length, briefly mentions the characteristics of the inhabitants of the various districts of Europe. If three variants (cephalic index, measurement of stature, and colour of skin and hair) be each classified under three headings, twenty-seven combinations may result: as a matter of fact only six occur in considerable numbers, while four more in lesser numbers. The conclusion that only six primary races (excluding Turks, &c.) inhabit Europe, with four secondary, the latter in smaller numbers and probably due to mixtures of the primary. These races he characterises and names:

(1) Blond, dolichocephalic, very tall ...	North-western race.
(2) Blond, sub-dolichocephalic, short	Eastern race.
(3) Brown, very dolichocephalic, very short	Ibero insular.
(4) Brown, very brachycephalic, short	Western race.
(5) Brown, sub-dolichocephalic, tall..	Atlanto-Mediterranean.
(6) Brown, brachycephalic, tall ...	Adriatic.

The four secondary races:

(α) Blond, mesocephalic, tall ...	Eastern Prussia.
(β) Blond, mesocephalic, very short...	Sweden.
(γ) Medium, sub-dolichocephalic, tall	Ireland, Belgium.
(δ) Auburn, sub-brachycephalic, medium	Holland to Bavaria.

THE first number of a new volume of *The Naturalist*, that old-established and admirable little monthly journal of natural history for the north of England, marks the disappearance of its former slate-grey wrapper and the substitution of a pink one, together with sundry improvements in type and setting, and the introduction of paper better adapted for illustrations. Altogether the editors are to be congratulated on the changes they have brought about.

WE have received from Messrs. Carl Zeiss, of Jena, a catalogue of microscopes and one of photographic objectives. The former does not describe any new kind of instrument, but in the latter an interesting feature is the new "Planar" lens. It is claimed that, with this, objective enlargements can be obtained of microscopic sections up to 100 diameters, so that it should prove extremely useful to botanists and others whose preparations demand the use of a lens having a large field and great covering power.

THE additions to the Zoological Society's Gardens during the past week include a Dingo (*Canis dingo*, ♂) from Australia, presented by Mr. D. R. McDowall; a Long-legged Buzzard (*Buteo ferox*), a Kestrel (*Tinnunculus alaudarius*), captured in the Red Sea, presented by Mr. J. Kilpatrick; a Golden-naped Amazon ((*Chrysotis auripalliata*) from Central America, presented by Mr. Gambier Bolton; two Red Ground Doves (*Geotrygon montana*) from South America, presented by Lady Blake; a Dinker Bok (*Cephalophus grimmi*) from West Africa, presented by Mr. L. H. Nott; a Salvadore's Cassowary (*Casuarius salvadori*) from New Guinea, a Salvin's Amazon (*Chrysotis salvini*), a Blue and Yellow Macaw (*Ara ararauna*), a Red and Yellow Macaw (*Ara chloroptera*) from South America, deposited; two Black Larks (*Melanocorypha peltoniensis*) from Siberia, purchased; two Axis Deer (*Cervus axis*, ♀ ♀), a Pink-headed Duck (*Rhodonessa caryophyllacea*, ♂), an Indian Crow (*Corvus splendens*), four Spotted Turtle Doves (*Turtur suratensis*), two Brown-headed Gulls (*Larus brunneicephalus*) from India, received in exchange.

OUR ASTRONOMICAL COLUMN.

PLANETARY RELATIONS.—In *Comptes rendus*, of January 17, M. Emile Anceaux gives a note on the four great planets, and some new deductions relating to them. The four great planets—Jupiter, Saturn, Uranus, and Neptune—possess between them more than 99/100 of the known planetary mass; whilst Jupiter and Saturn alone have a total mass greater than 9/10 of this. It seems natural, then, to consider the system of these four planets as a world apart and independent of the other planets relatively small, and separated by a band of telescopic planets smaller still. The author considered, therefore, whether, by reason of their importance, the masses of the four great planets would not have some influence upon their distribution with respect to their distances from the sun. Some of the most interesting deductions are as follows:—

The masses of Jupiter and Saturn are inversely proportional to the squares of the major axes of their orbits.

The mass of Jupiter is to the sum of the masses of Uranus and Neptune as the inverse square of the major axis of Jupiter's orbit is to the sum of the inverse squares of the major axes of Uranus and Neptune.

The mass of Jupiter is to the sum of the masses of the four planets as the inverse square of Jupiter's major axis is to the sum of the inverse squares of the major axis of the four planets.

The mean moments of inertia of Jupiter and Saturn referred to the sun are equal to each other.

The mean acceleration of the solar attraction on Jupiter is to the sum of the mean accelerations produced upon Uranus and Neptune as the mass of Jupiter is to the sum of the masses of Uranus and Neptune.

The reason of this harmony may be in the conditions of stability of the system, or in the circumstances which prevailed at the formation of the planets. If this last cause be possible, the study of these relations would not fail to throw some light upon the cosmogony of the solar system.

U PEGASI AND SHORT-PERIOD VARIABLES.—The telescopic variable known as U Pegasi, which was discovered by Chandler in 1894, has for a long time been thought to have the shortest period of all variable stars, but observations made at the Harvard College Observatory go to prove that this is not the case.

Prof. Pickering, in *Circular* No. 23, from the above Observatory, gives the results of the observations made by Mr. O. C. Wendell with the polarising photometer, and states that the discrepancies between various observers, as to the period of the star, made it desirable to determine the true form of the light curve photometrically.

Mr. Wendell began his observations on December 28 of last year, using, as comparison, the star + 15°·4916, mag. 8·90, which is only 15′ distant. From 2784 settings of the photometer he constructed a light curve, from which it soon became evident that alternate rather than successive minima were alike; the magnitudes at principal and secondary minima being 9·90 and 9·75 respectively. The light curve thus drawn, closely resembles in form that of β Lyræ, having nearly equal maxima, with magnitudes of about 9·30, and a period of 8h. 59m. 41s., the secondary minimum occurring nearly midway between the two primaries.

This period, it will be seen, is considerably different from that of 5h. 32m. 15s., as given by Mr. Chandler; but Prof. Pickering points out that, taking either value, the phases recur at nearly the same times every three days. If we neglect the difference between the primary and secondary minima, reduce the half-period to fractions of a day, and multiply it by 16, we obtain the product 2·99824d., or very nearly three days. If we multiply the period 5h. 32m. 15s. by 13, we obtain 2·99948d., or very nearly the same quantity. Accepting this new result, it appears that U Pegasi is no longer the variable star having the shortest period known. This position appears to be held by the variable ω Centauri 19, discovered by Prof. Bailey, who finds its period to be 7h. 11m. Although U Pegasi can no longer be regarded as an example of that peculiar class of short-period variables, having a single maximum in which the decrease is more rapid than the increase, this class is still represented not only by S. Antliæ, but by ω Centauri 24, which Prof. Bailey finds to decrease twice as rapidly as it increases, while ω Centauri 45 increases at least five times as fast as it diminishes.

WINNECKE'S COMET, *a* 1898.—The ephemeris of this comet is continued in the *Astronomical Journal* (No. 425) from February 7 to March 31, but for the purpose of observation it will suffice to give positions as far as the end of February; for after then the comet will be too near the sun to be conveniently observed.

Ephemeris for Greenwich Midnight.

Pleistocene origin, while that from Engis, described by Schmerling in 1833, is evidently much more recent. The origin of the well-known Neanderthal calvaria has always been doubtful, but its extraordinary heavy brows and low forehead gave it an interest at the time of its discovery, which is not lessened now that very similar skulls have been found under better authenticated conditions.

The Moulin Quignon jaw, which created so much discussion for a few years after its its discovery in 1863, has long since been put aside as lacking authenticity. But the jaw found by M. Dupont in the Naulette cave is accepted as that of a human being that lived with the mammoth. The human bones from the caves of Aurinac, Cromagnon, Frontal, Mentone, and some others were shown by Prof. Boyd Dawkins to be of neolithic age. The skeleton found at a depth of thirty-two feet at Tilbury Docks in 1883 was thought by Sir R. Owen to be of palæolithic age, but Mr. T. V. Holmes has shown that those gravels are of comparatively modern origin, and could not be older than neolithic.

A fresh impetus was given to the study of palæolithic man by the memoir of MM. Fraipont and Lohest, who in 1887 gave an account of two remarkable skeletons found at Spy, in the province of Namur, Belgium. These skeletons are accepted as of the same age as the extinct mammals, with the bones of which they were found associated. The skulls are of a low type, and one of them especially makes a very close approach to that from the Neanderthal, not only in the general form, but also in the great development of the brow ridges and the lowness of the forehead.

A single tooth from Pont Newydd cave, St. Asaph; a piece of a skull from the brick-earth of Bury St. Edmunds, and parts of a skeleton from the high terrace-gravel of Galley Hill, Northfleet, are believed to be the only well-authenticated instances of palæolithic human remains yet found in Britain; and it is only the skeleton last named that is sufficiently well-preserved to give any idea of the form of the skull or limb-bones. The Galley Hill skull is very long and narrow, the brow ridges are strongly developed and the forehead is low, but not so depressed as in the Neanderthal calvaria. Although it may not be correct to include the Java Pithecanthropus in the genus Homo, yet as it holds an intermediate position between the lowest type of human skull,—the Neanderthal—and that of certain apes, it cannot be neglected when considering the early progenitors of man and its position in the geological series at the beginning of the Pleistocene, if not in the Pliocene, is precisely the place where such an ancestor would be expected to appear.

Although the greater number of the human remains supposed to be of palæolithic age are now known to be of more recent origin or are not well substantiated, yet there are a few which may be accepted as in all probability representatives of the men who made the palæolithic implements. In the latter category may be placed the skeletons from Spy and that from Galley Hill, as well as the jaw from Naulette and the piece of skull from Bury St. Edmunds. The Eguisheim skull and a few other remains found on the continent of Europe should perhaps be included with these. The famous calvaria from Neanderthal and Canstadt are among the remains of uncertain origin, but, on account of their resemblance to the Spy skulls, are supposed to be of the same age, and to belong to the same race.

If we accept the Spy, and other skeletons, as the remains of the men who made the palæolithic implements, what do they tell us of the mental and physical condition of those early progenitors of mankind? As a gauge of intellectual capacity, we have to confess that their skulls tell us far less than do the relics of their handiwork.

Prof. Huxley's dictum regarding the Spy men was that "the anatomical characters of their skeletons bear out conclusions which are not flattering to the appearance of the owners." They were short and powerful, but must have walked with a bend at the knees. Their skulls were depressed, with strong brow ridges and lower jaws of brutal depth. The Neanderthal skull has been said by the same authority to be the most apelike of human crania yet discovered. At the same time it is highly probable that these palæolithic men were not less intelligent than some of the savage races living at the present day, for their brain capacity seems to have been as great as that of average Hottentots and Polynesians; and with an equal volume of brain we may presume there was an equal intellectual power. Moreover, men of no mean intellectual capacity are known to have possessed skulls of the Neanderthal type.

It may be doubted whether we are right in regarding the Neanderthal type of skull as typical of the palæolithic race, for other skulls referable to this period are less marked in character, and appear to indicate a greater range of form within the race than has usually been supposed. At present we have too few examples to allow of any definite deductions being made; but what we do know, points to the palæolithic race having had long skulls (dolichocephalic), in which particular they approach the neolithic race; but differ from them in the greater development of their brow ridges, in their lower and more receding foreheads, and in their shorter stature.

That palæolithic man possessed considerable mechanical skill, is shown by the well-fashioned flint implements that have been found; and the striking outlines of animals and men incised by him on pieces of ivory and bone, as well as the clever carvings in similar material, is evidence of no little artistic ability. And further, if we bear in mind how little of his work has been preserved to us, and how much that was perishable must have entirely disappeared, we shall be inclined to credit our palæolithic ancestors with a somewhat higher social status than we have usually supposed them to have enjoyed.

ALCOHOL IN RELATION TO MICROBIAL DISEASES.

THE effect of alcohol on the artificial production of immunity in animals in regard to rabies, tetanus, and anthrax has been recently studied by Dr. Deléarde. It has been frequently observed that persons addicted to alcohol suffer, as a rule, far more severely from the effects of microbial infections than normal individuals, and not long ago, in 1896, Abbot, of Philadelphia, showed that pathogenic bacteria, incapable of killing healthy animals, were able to produce fatal results in animals intoxicated with alcohol. This was found to be the case with the *B. coli communis*, the *staphylococcus*, and the *streptococcus*. Deléarde has turned his attention to the effect produced by alcohol on the artificial prevention of disease in animals; and, considering the great importance of the subject, it is to be regretted that his conclusions are drawn from so few experiments. It appears that a rabbit vaccinated against rabies, and then given considerable quantities of alcohol (introduced into the œsophagus by means of a tube) for several weeks, and subsequently inoculated with fresh rabid virus, did not succumb to rabies, whilst another rabbit treated similarly, only omitting the doses of alcohol, died of rabies. In this case the alcohol had apparently preserved the animal's immunity to rabies. On the other hand, a rabbit dosed with alcohol during the course of the anti-rabic inoculation, obtained absolutely no immunity from rabies; whilst a rabbit, first of all intoxicated and then vaccinated, acquired immunity to rabies as long as the supply of alcohol was stopped as soon as the vaccinations were commenced. In the case of tetanus, however, if the anti-tetanic inoculations were succeeded by the administration of alcohol, the animal lost all its artificially acquired immunity to the disease, and invariably succumbed to tetanus infection; again, if treated with alcohol during the vaccinations, it only acquired immunity to tetanus with difficulty, and if first of all intoxicated and then vaccinated, the animal obtained immunity as long as the supply of alcohol ceased when the vaccinations began. As regards anthrax, it is almost impossible, it appears, to protect animals from this disease if they are treated with alcohol during the vaccination period. On the other hand, animals first intoxicated and then vaccinated can acquire immunity providing, as in the other cases mentioned above, the alcohol is stopped as soon as the vaccinations are commenced, but they suffer considerably more during the process than animals which have received no alcohol. The experimental results obtained with rabies bear out the observations which have been made with regard to intemperate persons and the anti-rabic treatment in various Pasteur Institutes, and a very striking instance of the ineffectuality of the treatment in such a case was recorded only this year. An habitual drunkard was bitten by a mad dog, as was also a child by the same dog; both underwent precisely the same anti-rabic treatment. The man during the whole time continued to drink to excess, and subsequently died of rabies, whilst the child remained perfectly well. In the case of the administration of antitoxins it would appear, therefore, highly desirable that at least during the vaccinations alcohol should be prohibited.

STRIDULATION IN SOME AFRICAN SPIDERS.[1]

THE spiders which form the subject-matter of this paper, are probably best known by the comprehensive title "Mygale." They are also sometimes called crab-spiders, presumably from the great size to which most of the species attain; sometimes bird-eating spiders, from their alleged propensity for capturing and devouring small birds, a propensity which suggested to Lamarck the generic term *Avicularia*, still in use for one of the South American genera. But during the last fifty years our knowledge of this group has increased by leaps and bounds; the genus has expanded into a family, represented by numbers of genera which are rapidly becoming more and more accurately defined and classified.

Apart from their large size and usually heavy build, these spiders, referred to a family variously termed *Mygalidæ*, *Theraphosidæ* and *Aviculariidæ*, may be recognised from the vast majority of other spiders by possessing two pairs of lung-sacs, and by the circumstance that the mandibles or jaws project horizontally forwards; while the fang closes almost longitudinally backwards.

So far as habits are concerned, it may be added that none of the species spread nets for the capture of prey. Most of them live on the ground beneath stones, or in deep burrows which they excavate in the soil, and line with a layer of tough silk to prevent the infall of loose particles of earth or sand. At nightfall the spiders may be seen watching at the entrance of their burrows for passing insects, and during the breeding season the females are to be found at its further extremity mounting guard over their egg-cocoon. Other species again live in trees, and spin a silken domicile either between forked branches or in the hollow trunk, or in large leaves rolled up for the purpose. There is no doubt that their food consists almost wholly of insects of various kinds. Nevertheless cases are on record of the destruction of small reptiles, mammals, and birds by these monstrous spiders.

The discovery of stridulatory organs in the members of this family dates back to the year 1876, when Prof. Wood-Mason came across one in an Assamese species now known as *Musagetes stridulans*. Since that year organs like that which he described have been found, not merely in the solitary species as he and most of his successors appear to have thought would be the case, but in a great number of genera ranging from India to Queensland.

In some of the African *Theraphosidæ* Mr. Pocock has had the good fortune to discover two stridulating organs, which are not only quite different from each other, but also quite different from those possessed by the genera inhabiting Tropical Asia. One of these organs occurs in the genus *Harpactira*, the common "Mygale" of Cape Colony. It occupies the same position as the analogous organs existing in the Oriental species, being situated between the mandible and the maxilla. The other, on the contrary, found in *Phoneyusa* and its allies, is placed between the maxilla and the basal segment of the first leg.

What is to be said respecting the function of these organs, and what evidence, it may be asked, can be adduced in support of the view that they subserve stridulation? To this question the answer must be that so far as the African species are concerned there is no direct evidence based upon observation of the living animal to show what part they play in the spider's economy. But that their true and probably sole function is the emission of sound, is so strongly supported as to reach practical certainty from what is known of the function of the analogous organ detected by Wood-Mason in the Assamese genus *Musagetes*.

Observations have shown that the function of the instrument in spiders of this genus is to emit sound, so it may be concluded that organs constructed upon the same principle, and occupying the same or similar positions, will in all probability be found to perform the same office; and no further basis need be sought for the belief that the African spiders, *Harpactira* and *Phoneyusa*, and their allies, can stridulate as well as their Oriental relations.

What now is the use to the spider of the sounds that these organs give forth? It has been suggested that, like the call of the cicada and the chirrup of the cricket, they have a sexual significance, and serve to inform one sex of the whereabouts of the other. This belief, however, has no foundation in fact; for, in the first place, there is not a particle of evidence that these spiders possess an auditory sense; and, in the second place, these stridulatory organs are equally well developed in the males and females, and are not, like the sexual stridulating organs known in other groups, confined to the male, or at all events better developed in that sex than in the female. Moreover, they appear in the young at an early age, and become functionally perfected long before the attainment of sexual maturity. So the supposition that they act as a sexual signal may be regarded as unsupported by evidence.

As a matter of fact, the true key to their function is supplied by the behaviour of the living spiders. From observations by Mr. Peal and Mr. E. W. Pickard-Cambridge, it appears that the spiders emit the sound when on their defence and acting under the stimulus of fear or anger, in exactly the same way as the rattlesnake makes use of its rattle. Mr. Pocock points out that the only explanation that has been suggested touching the function of the snake's rattle is that it serves as an advertisement of the whereabouts of the poisonous reptile, so that it may be avoided by enemies which might otherwise inadvertently injure it. Similarly poisonous and noxious insects are decked with warning colours, so that they may be readily recognised and not slain in mistake for harmless or edible species. If this be the true explanation of the so-called warning coloration of the insects in question, and of the whirring noise made by the rattlesnake, there seems to be no reason to doubt that the same significance is to be attached to the stridulation emitted by the peculiar organs recently discovered in the great African spiders.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Professor of Mineralogy has been granted the sum of 50*l.* a year for five years, from January 1, to assist in the purchase of specimens and apparatus for his department.

Sir Archibald Geikie, F.R.S., will deliver the Romanes Lecture at the Sheldonian Theatre on Wednesday, June 1. His subject will be "Types of Scenery, and their Influence on Literature."

The Junior Scientific Club held its first meeting for this term on Wednesday, February 2. Mr. A. W. Brown exhibited and described some life specimens of *Aphrodite* and two specimens of the unsegmented Cestode, *Amphilina*. Mr. G. W. S. Farmer read a paper on "Training." Mr. A. E. Boycott (Oriel) is President this term.

CAMBRIDGE.—The Special Board for Biology have re-elected Dr. Arthur Willey to the Balfour Studentship for one year. The same Board have nominated Mr. K. R. Menon to occupy the University's table at the Naples Zoological Station.

Mr. W. W. Skeat, District Magistrate of Larut, Perak, has offered to the Ethnological Museum a collection of exceptional interest and scope, illustrative of the fast-disappearing indigenous crafts of Selangor and its neighbourhood.

Dr. G. Elliot Smith, advanced student of St. John's College, has been approved for the Certificate of Research. His original dissertations relate to the origin of the Corpus Callosum and to cerebral anatomy.

Mr. H. E. Durham, M.A., M.B., has been appointed one of the representatives of the University at the Madrid Congress of Hygiene, to be held in April next.

Sir E. Frankland has been appointed an Elector to the chair of Chemistry, Sir W. Turner an Elector to the chair of Anatomy, Prof. D. Oliver to the chair of Botany, Sir A. Geikie to the Woodwardian Professorship, Dr. Hugo Müller to the Jacksonian Professorship, Mr. L. Fletcher to the chair of Mineralogy, Lord Walsingham to the chair of Zoology, Lord Kelvin to the Cavendish Professorship, Sir W. H. White to the chair of Mechanism, Prof. Schäfer to the chair of Physiology, Lord Lister to the chair of Surgery, and Dr. J. F. Payne to the chair of Pathology.

IN the last paragraph of the Speech from the Throne, read at the opening of the new Session of Parliament, on Tuesday, it was announced that measures for the constitution of a teaching University for London, and for dealing in part with the subject of secondary education, would be brought forward "in case the time at your disposal should permit you to proceed with them." As several other measures are in the same case, the outlook is not very hopeful for either of the educational measures referred to, and unless the Government seriously pushes them forward another Session will pass without the much-needed legislation. The measures are urgently pressing for consideration, and they ought not to be permitted again to lapse, as they have done before.

---

[1] Abridged from an article by Mr. R. I. Pocock in the *Zoologist*, January 15.

THE *Lancet* announces that the Senate of Glasgow University have appointed Prof. Michael Foster to be Gifford Lecturer in the Glasgow University for the sessions 1898-99 and 1899-1900, in succession to Prof. Bruce, whose term of office expires with the current session.

THE students of Finsbury Technical College will hold their annual conversazione at the College on February 18. Prof. S. P. Thompson has promised to lecture on "Wireless Telegraphy." Mr. Ives will give an exhibition of colour photography, and glow-lamp making will be demonstrated by Mr. Robertson.

AN illustrated article on technical education in the United States, together with some other statistics relating to the occupations of students who have passed through certain representative American institutions, appears in the January *Record of Technical and Secondary Education.* Among other articles we notice one on technical instruction given to fishermen in Aberdeenshire and Essex.

THE following item of information from the tenth annual report (1897) of the Clerkenwell Public Library, London, is worth recording:—"Scientific works are very largely circulated. Biology, including evolution and methods of scientific research, is a very popular subject, the sixty-eight works which the library contains on this topic having been issued over 2800 times within recent years. In this subject two copies of Darwin's 'Descent of Man' have been issued nearly 200 times, a record which is exceeded only by the most popular novels."

DR. W. B. BENHAM, M.A., New College, Oxford, has been elected to the chair of Biology in the University of Otago, and will leave England at the end of March. Dr. Benham has for the past seven years held the post of "Aldrichian Demonstrator in Comparative Anatomy" at Oxford, and as such has acted as assistant to Prof. Lankester, to whom he was previously assistant in University College, London. For ten years Dr. Benham has been Lecturer in Animal Biology at Bedford College for Women, London; and was appointed Examiner in Zoology in the University of London last year. His original researches are embodied in some thirty papers: these are mainly concerned with the anatomy and classification of the Oligochæte Annelids; he has also contributed the article "Polychæta" to the Cambridge Natural History, and published an account of the Brain of the Chimpanzee "Sally," the Blood of *Magelina*, the Anatomy of *Phoronis*, &c.

AT the annual congress of the South-eastern Union of Scientific Societies, held at Tunbridge Wells last May, Mr. S. Atwood, of New Brompton Natural History Society, drew attention to the difficulty of securing rooms for meetings in some of the smaller towns, even where suitable rooms belonging to Technical Institutes existed, which the Societies would be willing to hire. On the proposition of Mr. Pankhurst, of Brighton, the following resolution was passed unanimously:—"That it be an instruction to the Council of this Union to consider the question of how far buildings erected under or used for the purposes of the Technical Institution Acts may be made available for the use of local scientific societies." Since then the Council have had the matter under consideration, and have communicated with Colonel Holland, of the Kent County Council, who has replied to the effect that the Technical Education Committee have no control over Technical Institutes, and the local authority must be applied to for the permission desired. Colonel Holland adds: "If that authority wishes to help, it can do so without any permission from the Technical Education Committee." It appears, therefore, that no legal obstacle exists to the use of rooms belonging to or used for the purposes of technical instruction when such rooms are not needed for their special objects.

IN a paper on the teaching of science in secondary schools, read on January 12, in Birmingham, before the Friends Guild of Teachers, Dr. Bevan Lean deprecated children beginning systematic work in science or entering the laboratory before the age of thirteen or fourteen, and urged that before boys (and girls) were allowed to learn chemistry or physics they should possess at least a sound knowledge of arithmetic. It was emphasised that the teaching of science in schools should not be in any sense commercial, nor should its aim be the mere awakening of interest or even the gain of knowledge: it was valuable solely as a means of mental culture, because through it could best be stimulated the power of accurately ascertaining facts and drawing correct inferences. It was urged that this educational value could best be obtained through chemistry, because chemistry admitted of quantitative experiment within the time of a short class and of an infinite variety of experiment; and, moreover, it so frequently touched matters and operations that were familiar to children in every-day life. The scientific method of investigating nature must be illustrated, and that necessitated placing the children in the attitude of discoverers, so that they could proceed from the known to the unknown, and not from the simple to the complex. Experience showed, too, that the problems on which great investigators were engaged 100 years ago were suitable for the modern schoolboy. This did not mean that we could build up the whole of our science for ourselves. The time for books and lectures would come, but at school it was far more important that boys and girls should be placed in direct contact with facts in the attitude of inquirers. It was a necessary corollary that the teacher ought to have a knowledge of the history of his science, and that it would be a great advantage if he had himself carried on original research: at the least, he ought to have an inveterate habit of inquiry.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, January.—On the commutator groups, by Dr. G. A. Miller. This is a collection of eleven theorems, some of which are proved in the present paper. For proofs of the remaining theorems reference is made to the writings of Frobenius and Dedekind. Dr. G. A. Miller has also a paper, read before the Society at its December meeting, entitled "On the limit of transitivity of the multiply transitive substitution groups that do not contain the alternating group." This is a paper which contains three theorems and four lemmas bearing upon results recently given by Jordan and Bochert in *Liouville's Journal* and the *Mathematische Annalen* respectively.—Geometry of some differential expressions in hexaspherical coordinates, by Dr. V. Snyder, read at the Toronto meeting, is an appendix to the author's dissertation "Ueber die linearen Complexe der Lie'schen Kugel geometrie" (Göttingen, 1895). It gives an outline of differential geometry, and shows the application of it to the quadratic complex. Some results are, among the ∞^3 spheres which touch a given surface, there are ∞^2 which also cut a fixed sphere at a constant angle. These spheres either envelope another surface or are arranged in ∞^1 pencils, touching the surface along the curve of intersection with the sphere, which is then a line of curvature of the given surface (*cf.* Darboux, "Théorie des surfaces," vol. i. p. 257, who does not mention the exceptional case). The locus of the point-sphere in a spherical complex of degree n is a surface of degree $2n$, and contains the circle at infinity as an n-fold line. The surface of singularities of a quadratic spherical complex is a cyclide. The Dupin cyclide is the only surface that can be the complete envelope of a non-reducible special quadratic spherical complex. Numerous references are given to writers on the subject.—Dr. E. O. Lovett gives a useful abstract of some lectures by Sophus Lie, viz. "Vorlesungen über Differentialgleichungen mit bekannten infinitesimalen Transformationen" (edited by Dr. G. Scheffers, Leipsic, 1891).—Dr. Charlotte A. Scott, in a short note, commends a translation of Prof. Klein's "Vorträge über ausgewählte Fragen der Elementargeometrie," by Messrs. W. W. Beman and D. E. Smith.—The "Notes" and "New Publications" give their usual useful information.

Bulletins of the St. Petersburg Society of Naturalists, 1897 (xviii.), Nos. 2 and 3, February and March.—No. 2.—Geological excursion in North Russia, by Amalitzkiy.—Age of clay slates on the Upper Ulba, Altai, by von Petz.—Excursion to Crimea (botany), by Levandosvkiy.—On the part played by iron on the motions and the degeneration of cells when they are submitted to the bactericidal action of the immunised serum, by Sakharoff.—On fertilisation in *Juglans regia* and *J. nigra*, by Navashin.

No. 3.—On the relations between the Upper Tertiary in Russia, Rumania, and Austro-Hungary, by Andrusoff.—Journey to East Persia (geo-botany), by Korovyakoff.—All these communications are fully summed up in French or German.

SOCIETIES AND ACADEMIES.

London.

Royal Society, January 20.—"The Homogeneity of Helium." By William Ramsay, Ph.D., LL.D., Sc.D., F.R.S., and Morris W. Travers, B.Sc.

About a year ago, a paper by Dr. Norman Collie and one of the authors (W. R.) was published, bearing the title "The Homogeneity of Helium and of Argon." In that paper (Nature, 1896, p. 546) various reasons were adduced to show why an attempt to determine whether or no argon and helium are homogeneous was worth making. The results of the experiments at that time indicated that while it did not appear possible to separate argon into two portions of different densities, the case was different with helium. Samples were obtained after repeated diffusion which possessed respectively diffusion rates corresponding to the densities 2·133 and 1·874. It was there pointed out that these densities are not correct (although their ratio is probably not wrong), owing to the curious fact that the rate of diffusion of helium is too rapid for its density, *i.e.* it does not follow Graham's law of the inverse square root of the densities. These samples of gas also differed in refractivity, and the difference was approximately proportional to the difference in density.

Towards the end of the paper, the conjecture was hazarded that it was not beyond the bounds of possibility that the systematic diffusion of what we are accustomed to regard as a homogeneous gas, for example, nitrogen, might conceivably sift light molecules from heavy molecules. It is true that the fineness of the lines of the spectrum would offer an argument in favour of the uniformity of molecular weight; but still it is never advisable to assume any physical theory without submitting it to rigorous proof. And it was thought possible that the fractional diffusion to which helium had been subjected might have had the result of effecting such a separation; a separation, not of chemical species, but of molecular magnitude. The other and more ordinary explanation of the splitting of helium into fractions of different density is that helium must be regarded as a mixture of two gases, one lighter than the other.

Since the publication of the paper mentioned, Dr. A. Hagenbach has confirmed the possibility of separating helium into portions of two densities by diffusion; and the differences in density were practically the same as those observed in the laboratory of University College, London.

These experiments were made with somewhat over 200 c.c. of gas; but it was decided to make experiments of a similar kind, on a much larger quantity of helium.

An apparatus was therefore constructed, similar in principle to the one previously employed, but on a much larger scale.

The Fractional Diffusion of Air.

In order to test the working of the apparatus, a set of diffusions was carried out with air. After four rounds, comprising twenty-four diffusions, the light portion contained 17·37 per cent. of oxygen and the heavy portion 22·03. A fairly rapid separation was thus being effected considering the closeness of the densities of nitrogen and oxygen.

The Fractional Diffusion of Nitrogen.

A similar set of experiments was carried out with nitrogen, prepared by the action of solutions of ammonium chloride on sodium nitrite, in presence of copper sulphate. The gas was dried and passed over red-hot iron prepared by reduction of ferric oxide in order to remove any oxygen or to decompose any oxides of nitrogen which might be present. After thirty rounds, involving 180 operations, the "light" portion of the nitrogen, after purification by circulation over copper oxide, had not altered in density. It must therefore be concluded that nitrogen is homogeneous as regards the relative density of its individual molecules.

The Fractional Diffusion of Helium.

The first sample of helium employed was prepared from samarskite and clèveite. After seventeen rounds, involving 102 operations, the diffusion rates of the lighter and heavier portions were measured.

A fresh quantity of gas from clèveite was similarly treated.

The light gas from the first set of diffusions was then mixed with the light gas from the second set of diffusions and the mixture was re-diffused fifteen times, involving ninety operations. The density of the lightest portion of this helium was determined by weighing and found to be 1·988. The helium had, therefore, not been made sensibly lighter by re-diffusion. The mean of the two determinations may be taken as the true density of pure helium; it is 1·98. The refractivity of this sample measured against hydrogen and multiplied by the ratio between hydrogen and air, viz. 0·4564, gives 0·1238. This specimen of light helium of density 1·988 was placed in one of the refractivity tubes, and the lightest helium of the former preparation (density = 1·979) in the other. They had the same refractivity (1000 to 1004). The contents of No. 1, obtained from the mixture of light gases, had the density 2·030, showing that only a little heavier material had been withdrawn.

The lighter fractions of helium were then sealed up in glass reservoirs and stored. The heavier portions were placed in the diffusion apparatus and submitted to methodical diffusion.

After fifteen rounds (ninety operations) the heaviest fraction had density 2·275, the lightest 2·08. The refractivity of the heaviest gas was next determined and found to be 0·1327. This gas examined in a Plücker's tube showed brilliantly pure helium lines, but along with these the reds and green groups of argon. Calculating from the density of this gas it should contain 1·63 per cent. of argon according to the equation $1\cdot961x + 20y = 2\cdot275$. Calculating from the refractivity the percentage of argon should be 1·05, from the equation $1\cdot245x + 0\cdot9596y = 13\cdot33$. A mixture of 99 per cent. of the purest helium and 1 per cent. of argon was made, and it showed the argon spectrum with about the same or with somewhat less intensity than the heaviest gas. Finally, the heavy gas was diffused to the last dregs, so that only about 0·5 c.c. remained undiffused; and this small residue, transferred to a Plücker tube, showed the argon spectrum with only a trace of the spectrum of helium. The yellow line and the bright green line were visible, but feeble. This spectrum was compared with that of a mixture of argon with a trace of helium, and nearly the same appearance was to be seen. With the jar in parallel and a spark gap interposed the blue spectrum of argon was equally distinct in both tubes; and, more important still, *there was no trace of any unknown line*. It appears, therefore, that helium contains no unknown gas, nor is it possible to separate it by diffusion into any two kinds of gas; all that can be said is that most minerals which evolve helium on heating also evolve argon in small quantity. This accounts for the difference in density observed in different samples of helium; and in one instance, viz. malacone, the amount of argon evolved on heating the mineral, though small, was much in excess of the helium, so far as could be judged by the spectrum.

We are disappointed in the result of this long research, because we had thought it not improbable that an element of density 10 and atomic weight 20 might prove to be the cause of the fact that different samples of helium possess different densities, according to the mineral from which they are extracted, and also of the separation of helium into portions of different densities by diffusion. We still regard it as by no means improbable that further research will lead to the discovery of the "missing" element.

Addendum.—Since this paper was written, Profs. Runge and Paschen, in a communication to the British Association in August of last year, have withdrawn their contention that helium is a mixture, or, perhaps more correctly stated, they now ascribe to helium the same complexity as that of oxygen, the spectrum of which may also be arranged in two series, each consisting of three sets of lines. As oxygen has not yet proved to be complex, the surmise that helium is complex therefore falls to the ground.

Chemical Society, January 20.—Prof. Dewar, President, in the chair.—A ballot for the election of Foreign Members was held and Profs. S. Arrhenius, P. Curtius, A. P. N. Franchimont, W. Körner, W. Markownikoff, N. A. Menschutkin, H. Moissan, W. Ostwald, F. M. Raoult, I. Remsen, W. Spring, L. J. Troost, P. Waage and J. D. van der Waals were subsequently declared duly elected.—The following papers were read:—The preparation of pure iodine, by B. Lean and W. H. Whatmough. Pure iodine is conveniently prepared by heating cuprous iodide in a stream of dry air at 220–240°; it melts at 112·5–114°.—Derivatives of bromtolylhydrazine, by J. T. Hewitt and F. G. Pope.—Researches on the terpenes. (1) On the oxidation of fenchene, by J. A. Gardner and G. B. Cockburn. On oxidising fenchene with dilute nitric acid, cis-camphopyric acid and its anhydride are formed. Turpentine hydrochloride, when oxidised with nitric acid, yields camphoric and camphopyric acids.—The action of alkalis on amides, by J. B. Cohen and C. E. Brittain. The authors have succeeded in preparing a series of compounds, which probably have the constitution $NNaR.C.Me(OH)_2$, by the action of caustic alkalis on amides.—The formation of monomethylaniline from dimethylaniline, by J. B. Cohen and H. T. Calvert. Phenylnitrocarbinol acts violently upon dimethylaniline with formation of nitrosomethylaniline, benzylic alcohol and benzaldehyde and evolution of nitrogen.—Note on the aluminium-mercury couple, by J. B. Cohen and H. T. Calvert. A small quantity of chlorine is retained by aluminium, probably as oxychloride, when it is amalgamated with mercuric chloride.—Action of chloroform and alkaline hydroxides on the nitrobenzoic acids, by W. J. Elliott.

Geological Society, January 19.—Dr. Henry Hicks, F.R.S., President, in the chair.—On some gravels of the Bagshot district, by Horace W. Monckton. The author referred to his papers on gravels south of the Thames, published in the *Quart. Journ. Geol. Soc.* for 1892 (p. 29) and 1893 (p. 308), and gave some additional details. He suggested that the occurrence of stones which had been very little rolled or waterworn in gravels at certain localities, afforded evidence of the presence of ice in the water by which those gravels were deposited; and that the position of some sarsens which he described was due to the same agency. He gave details and exhibited photographs of a number of sarsens which he had seen *in situ*. In the discussion which followed the reading of the paper, the hypothesis advanced by the author was criticised unfavourably by several speakers, but others supported it.—On the occurrence of chloritoid in Kincardineshire, by George Barrow. The rock containing the chloritoid was first found *in situ* at the entrance to the little gully at the head of Friar Glen Burn, near Drumtochty Castle. It has since been observed at many places along a belt of country extending from the coast north of Stonehaven nearly as far as the North Esk. The rock is easily recognised by the presence of numerous white spots, which are always present and are larger than the chloritoid. The chloritoid and the spots vary in size, being largest when the rock is most crystalline (a schist), and smallest when it is least crystalline (a slate). The mineral appears as minute glistening scales in the schist, but in the slate it can be recognised only with the aid of the microscope. The optical characters were described, and shown to be identical with those of the mineral from the Ile de Groix, and with those of the ottrelite from Ottré and Serpont. An account of the methods adopted to obtain a pure sample was given. Several analyses were made, and it was proved that as the purification increased, the analyses approximated more and more closely to the analysis of the mineral from the Isle de Groix. The final result was as follows:—SiO_2 26·00, Al_2O_3 40·05, FeO 19 50, Fe_2O_3 5·05, MgO 2·88, loss on ignition 6·00; total, 99·48.—The annual general meeting of the Society will be held on Friday, February 18, at 3 p.m.

Linnean Society, January 20.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—Mr. J. E. Harting exhibited a series of photographs of the grey seal (*Halichærus grypus*) at various ages, taken from life by Mr. Henry Evans, of Jura, on the Haskeir Rock, Outer Hebrides, to which place the animal resorts every autumn for breeding purposes. Some of the photographs showed the young thickly clothed with white hair, which is retained for several weeks after birth, but is gradually shed before the animal enters the water. Details of measurement and weight were given, and occasion was taken to review the status of the grey seal as a British species, and to indicate its known breeding stations in the British Islands.—Mr. W. J. H. McCorquodale exhibited a skull of a hartebeeste which was one among some fifty skulls of various ruminants he had recently received, all having their horns infested by the larvæ of *Tinea vastella*, upon the chrysalids of which he offered some remarks. The collection was from Nigeria, and was made by his brother the late Lieut. R. H. McCorquodale, 3rd Dragoon Guards, while doing duty as a special service officer in W. Africa. He further recorded the capture by his brother, in 1896, of a giraffe from the regions of the Benue River, north of Calabar, remarking that the specimen was the only one known from this region of Africa, and that its skull was now deposited in our national collection.—Mr. W. E. de Winton, who was present as a visitor, made some remarks on the geographical distribution of the giraffe in Africa, and traced the limits of the range of the northern and southern species as far as had been ascertained.—Dr. W. G. Ridewood read a paper on the larval hyobranchial skeleton of the anurous batrachians, in which were recorded observations made on twenty-one species belonging to nineteen genera.—Mr. R. H. Burne read a paper on the *porus genitalis* of the *Myxinidæ*, in which he concluded that the urogenital sinus present in the lampreys is in the *Myxinidæ* unrepresented, and that the ureters and genital pore open into an integumentary cloaca.

PARIS.

Academy of Sciences, January 31.—M. Wolf in the chair.—Note accompanying the presentation of the notice on the scientific work of H. Fizeau, by M. A. Cornu.—On the approximate development of the disturbance function, by M. H. Poincaré.—On the meteorological observatories of the Atlantic Ocean, by S.A.S. Albert, Prince of Monaco. Two centres of observation, at San Miguel and Flores, have been established in the Azores, and the results are regularly telegraphed to certain continental observatories. The observations from these two stations gives some fifty hours' warning to European ports of approaching depressions.—Remarks by M. Mascart on the preceding paper.—M. Cremona was elected a Correspondent in the Section of Geometry in the place of the late M. Brioschi.—Martial function of the liver in the Vertebrates and Invertebrates, by M. Dastre. The hepatic organ whenever present is always distinguished from the other tissues by the increased amount of iron it contains. Thus in the Crustacea the liver is rich in iron, containing four times as much as muscle, the blood and ovary containing practically none. In Molluscs (cephalopods) the hepato-pancreas contains, weight for weight, twenty-five times as much iron as any of the other tissues; in Lamellibranchs the ratio is about five to one, and the same for Gasteropods. The presence of this iron is independent of the metal in the blood, thus where copper is present in the blood as hæmocyanine, iron only is present in the hepatic tissue.—Observations of the periodical comet of Arrest, made at the Observatory of Rio de Janeiro with the 25 c.m. equatorial, by M. L. Cruls.—On some photographs of nebulæ obtained at the Observatory of Meudon, by M. A. Rabourdin.—Remarks on the preceding communication, and on the correct method of getting comparable images of the nebulæ, by M. J. Janssen. A telescope was specially designed for this work, of 1 metre aperture and 3 metres focal length. Owing to its very short focal distance this instrument is very valuable for observing and photographing very faintly luminous objects, especially nebulæ.—On the development of analytical functions for real values of the variables, by M. Painlevé.—On the systems of partial differential equations, analogous to systems of equations of the first order, by M. Jules Beudon.—On the relations between the infinitesimal elements of two homographic or correlative figures, by M. A. Demoulin.—On surfaces applicable to a surface of revolution, by M. A. Pellet.—On the decomposition of Θ-functions into factors, by M. G. Humbert.—On the most general monographic method resulting from the relative position of two superposed planes, by M. Maurice d'Ocagne.—On the permanent changes of form and breaking of metals, by M. G. A. Faurie. Test pieces of metals, submitted to longitudinal stress under certain conditions, develop nodal points at equal distances apart. These effects are not produced by bending or torsion.—On the flexion of thick bars, by M. Ribière.—Experimental study of the lustre of projectors of light, by MM. A. Blondel and J. Rey.—Study of some radiations by interferential spectroscopy, by MM. A. Perot and Ch. Fabry. By means of the interference apparatus described in previous papers, it is now shown that the green thallium ray is composed of one bright ray and of two others, more faint, situated towards the red. The bright green ray of mercury is also triple, two of these three lines being separated by only $\frac{1}{100}$th of the interval between the sodium lines. Some of the cadmium lines were also split up.—On the measurement of high temperatures by the interference method, by M. Daniel Berthelot. The method is based upon the fact that if the density of a gas is diminished to the same extent on the one hand by a rise of temperature, or on the other by a diminution of pressure, the index of refraction has the same value in both cases. The constant temperature required in these experiments was obtained by means of an electric furnace, composed of two spirals of platinum wire, jacketed with asbestos, by which any temperature up to 1000° C. could be steadily maintained.—On the composition of air at different places, and on the density of gases, by M. A. Leduc. After discussing the errors inherent to the methods of Dumas and Regnault, figures are given for the composition by weight of air taken at various places and under varying conditions of wind. The author notes that in comparing the densities of various gases with oxygen the figures obtained by himself and Lord Rayleigh agree very exactly, but that compared with air there is a constant difference of about ·0001, and hence concludes that the air of London contains 0·1 per cent. less oxygen than that of Paris.—New researches relating to the influence of the X-rays upon the explosive distance of the electric spark, by M. S. Guggenheimer.—On the Hertz resonator, by M. Albert Turpain.—On the decomposition of sulphite and hyposulphite of strontium by heat, and the production of phosphorescent strontium sulphide, by N. J. R. Mourelo.—Contribution to the study of oxydase in grapes. Its utility in the preparation of wine, by MM. A. Bouffard and L. Semichon. By the application of oxydase, white wines may be prepared from red grapes.—Phyllocyanic acid and the phyllocyanates, by M. A. Guillemare.—On the destructive action of a blood serum upon the red corpuscles of another species of animal. Inmunisation against this action, by MM. L. Camus and E. Gley.—Tyrosin, a chemical vaccine against snake poison, by M. C. Phisalix. This is the first known case where the cell sap of a plant confers immunising properties against snake poison.—The neurology of the encephalon in fishes, by M. Catois.—On the morphological limits of the rings of the integument, by M. Charles Janet.—On the fresh-water fauna of the Canary Isles, by M. Jules Richard. Among the species observed the following were the most remarkable: *D. similis*, var. *Alluadi*, and *Canthocamptus palustris*.—On the area of dispersion of the malacological fauna at great depths in the Atlantic, by M. Arnould Locard.—On the germination of the spores of the truffle, and the production of teleutospores, by M. A. de Gramont de Lesparre. The stages of germination are shown in nine diagrams.—On the age of the quaternary gravels of Villefranche (Rhône), by M. Gaillard.—On a new method for determining the position of foreign bodies by radiography, by M. H. Morize.

DIARY OF SOCIETIES.

THURSDAY, FEBRUARY 10.

ROYAL SOCIETY, at 4.30.—Contributions to the Theory of Alternating Currents: W. G. Rhodes.—The Development and Morphology of the Vascular System in Mammals. I. The Posterior End of the Aorta and the Iliac Arteries: Prof. A. H. Young and Dr. A. Robinson.—Further Observations upon the Comparative Chemistry of the Suprarenal Capsules: B. Moore and Swale Vincent.—The Effects of Extirpation of the Suprarenal Bodies of the Eel (*Anguilla anguilla*): Swale Vincent.

MATHEMATICAL SOCIETY, at 8.—The Transformations which leave the Length of Arcs on any Surface Unaltered: J. E. Campbell.—On Aurifeuillians: Lieut.-Colonel Cunningham, R.E.

INSTITUTION OF MECHANICAL ENGINEERS, at 7.30.—Report of the Council.—*Discussion upon* Mr. Philip Dawson's *Paper on* Mechanical Features of Electric Traction.

FRIDAY, FEBRUARY 11.

ROYAL INSTITUTION, at 9.—The Metals used by the Great Nations of Antiquity: Dr. J. H. Gladstone, F.R.S.

ROYAL ASTRONOMICAL SOCIETY, at 3.—Annual General Meeting.

PHYSICAL SOCIETY, at 5.—Annual General Meeting.—Address by the President.—Also Paper: On Electromagnetic Induction in Plane, Cylindrical, and Spherical Current Sheets, and its Representation by Moving Trails of Images: Prof. G. H. Bryan, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Protection of Power Transmissions from Lightning: John T. Morris.

INSTITUTION OF MECHANICAL ENGINEERS, at 7.30.—First Report to the Gas-Engine Research Committee: Description of Apparatus and Methods, and Preliminary Results: Prof. Frederic W. Burstall.—Steam Laundry Machinery: Sidney Tebbutt.

MALACOLOGICAL SOCIETY, at 8.—Descriptions of Two New Species of *Clausilia* from the Province of Che-Kiang, China: E. R. Sykes.—List of the Species of *Cataulus* found in Ceylon, with Descriptions of some New Land Shells from that Island: E. R. Sykes.—Notes on the Genus *Coxiella*: E. A. Smith.—Note on *Cypræa caput-anguis*, Philippi, with the Description of a New Variety of *C. caput-serpentis*: Mrs. A. F. Kenyon.

MONDAY, FEBRUARY 14.

SOCIETY OF ARTS, at 8.—The Principles of Design in Form: Hugh Stannus.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—A Recent Journey in Western Australia: Hon. David W. Carnegie.

IMPERIAL INSTITUTE, at 8.30.—Sierra Leone: Lieut. J. P. Mackesy, R.E.

TUESDAY, FEBRUARY 15.

ROYAL INSTITUTION, at 3.—The Simplest Living Things: Prof. E. Ray Lankester, F.R.S.

ZOOLOGICAL SOCIETY, at 8.30.—On the Osteology of the Steganopodes: W. P. Pycraft.—*On the Skeleton of the Regenerated Limbs of the Mid-wife-Toad* (*Alytes obstetricans*): Dr. W. G. Ridewood.—Description of a New Sea-Snake from Borneo: G. A. Boulenger, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Stability of Channels through Sandy Estuaries: P. M. Crosthwaite.

ROYAL STATISTICAL SOCIETY, at 5.—Democratic Statistics of the United Kingdom: their Want of Correlation and other Defects: Edwin Cannan.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Process Reproduction from an Editor's Point of View: Wallace L. Crowdy.

ROYAL VICTORIA HALL, at 8.30.—Brains: Hugh de Haviland.

WEDNESDAY, FEBRUARY 16.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Report on the Phenological Observations for 1897: Edward Mawley.—Monthly and Annual Rainfall in the British Empire, 1877 to 1896: John Hopkinson.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Essay on Micro-crystallography, with Lantern Illustrations: T. C. White.—Exhibition of Miscellaneous Lantern Slides: J. E. Barnard.

ENTOMOLOGICAL SOCIETY, at 8.—On the Genus *Erebia*: H. J. Elwes and Dr. T. A. Chapman.

THURSDAY FEBRUARY 17.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: On the Depletion of the Endosperm of the *Hordeum vulgare* during Germination: H. T. Brown, F.R.S., and F. Escombe.—On the Connection between the Electrical Properties and the Chemical Composition of Different Kinds of Glass: Prof. A. Gray, F.R.S., and Prof. J. J. Dobbie.—Contributions to the *Mathematical Theory of Evolution. On the Inheritance of the Cephalic* Index: Cicely Fawcett and Prof. K. Pearson, F.R.S.

ROYAL INSTITUTION, at 3.—Some Italian Pictures at the National Gallery: Dr. Jean Paul Richter.

SOCIETY OF ARTS (Imperial Institute), at 4.30.—The Plague in Bombay: Dr. Herbert Mills Birdwood.

SIMPSON AND CHLOROFORM.

Sir James Young Simpson and Chloroform (1811-1870). By H. Laing Gordon. 8vo. Pp. xii + 233. (London: T. Fisher Unwin, 1897.)

THIS is the third volume of an important series entitled "Masters of Medicine," of which two volumes have already been issued under the editorship of the late Mr. Ernest Hart. The series is intended to contain the lives of men, both of this and other countries, who have done much to advance the science and art of medicine; and the introduction of chloroform is so intimately associated with the name of Sir James Simpson, that any series of the "Masters of Medicine" would be incomplete if it did not contain an account of one who was largely responsible for the general employment of this anæsthetic.

James Young Simpson was born in the year 1811 at Bathgate, a village in Linlithgowshire, where his father, David Simpson, was the local baker and farrier; he was the seventh son, and great things were foretold of him.

He attended the village school, and even as a boy, under the superintendence of his master at school, studied the archæological features of the neighbourhood, and this study he continued later when he attended Edinburgh University, where he was sent by the unselfish assistance of his brothers Alexander and John, who, after he was qualified, found the means to send him abroad.

At college his life was much influenced by his two friends MacArthur and Reid, who had, by their example and precept, much to do with his greatness in the future. In 1838 he became in Edinburgh an independent lecturer on midwifery; and in 1839, although only twenty-eight years of age, he applied for the professorship made vacant by the resignation of Prof. Hamilton. Finding his chance of obtaining the chair as a bachelor would be small, he went to Liverpool and returned with Miss Jennie Grindlay as his wife; and although the professors were opposed to his being appointed, he was elected by the Town Council with the narrow majority of one vote. As a professor he attracted not only the students of the college, but older men who came to hear the recently despised subject of midwifery dealt with in a masterly and scientific fashion.

The increased fame and, in consequence, the increased work attached, did not affect Simpson's homely life. He found time to take pleasure in the companionship of his friends and relatives. It was his custom to keep open house both at breakfast and luncheon time, but his evening meal was reserved that he might enjoy the intimacy of his own family.

It was in 1850 that Simpson took part in the great controversy on the merits of homœopathy, which he condemned as irrational, and it was through him to a great extent that homœopathy was thoroughly crushed in Edinburgh.

Prof. Simpson's versatility was remarkable. He was able to discuss any subject in literature, science, politics or theology; but it was in archæology that he did most work outside his profession. He had correspondents in different parts of Scotland engaged in making researches into antiquities, and in 1861 he became President of the Society of Antiquaries of Scotland.

It is, however, with chloroform that the name of Simpson will chiefly be associated. To many people chloroform is anæsthesia, and the previous introduction of ether is often ignored. It is, therefore, hardly superfluous to repeat that ether was introduced in 1842 by Mr. W. T. G. Morton, a dentist of Boston, Massachusetts; its use rapidly spread, and it was employed extensively in America, Great Britain and abroad. The administration of ether was not unattended with difficulties; the methods employed at that day would now be considered extremely crude, and many—both surgeons and chemists—were looking eagerly for a simple and more convenient anæsthetic; and Simpson, although at this time much occupied with his increasing practice, gave all his leisure to testing for himself the effects of numerous drugs. After innumerable failures he, together with Dr. George Keith and Dr. Matthew Duncan, on November 4, 1847 at last tried chloroform, which was suggested to them by Mr. Waldie, a chemist of Liverpool, but had been discovered and described in 1831 by Soubeiran and Liebig independently. We may quote here the account given of the first employment of chloroform as an anæsthetic:—

> "Immediately an unwonted hilarity seized the party—they became bright-eyed, very happy, and very loquacious—expatiating on the delicious aroma of the new fluid. The conversation was of unusual intelligence and quite charmed the listeners—some ladies of the family and a naval officer, brother-in-law of Dr. Simpson. But suddenly there was a talk of sounds being heard like those of a cotton-mill louder and louder; a moment more and all was quiet—and then crash! On awakening Dr. Simpson's first perception was mental. 'This is far stronger and better than ether,' said he to himself. His second was to notice that he was prone on the floor, and that among his friends about him there was both confusion and alarm.
>
> "Hearing a noise he turned round and saw Dr. Duncan beneath a chair—his jaw dropped, his eyes staring, his head bent half under him; quite unconscious, and snoring in a most determined and alarming manner. More noise still and much motion. And then his eyes overtook Dr. Keith's feet and legs making valorous efforts to overturn the supper table, or more probably to annihilate everything that was on it. By and by Dr. Simpson having regained his seat, Dr. Duncan having finished his uncomfortable and unrefreshing slumber, and Dr. Keith having come to an arrangement with the table and its contents, the sederunt was resumed."

It is Simpson, too, whom we have to thank for fighting those who found in the practice of anæsthesia something which was contrary to their beliefs or principles, and for making the giving of anæsthetics an every-day occurrence; and we can hardly at the present day imagine the little-mindedness displayed by those who endeavoured, fortunately without success, to oppose the employment of anæsthetics.

About ten years after the introduction of chloroform he turned his attention to wound healing; at this time bleeding was arrested by tying the cut arteries with ligatures, and the ends of these were left hanging out of the wound. In 1858 Simpson stated that he had made use of iron, silver, and platinum wires, and after ten years' research he was led to the introduction of acupressure, which essentially consisted in the passing of a fine needle through the tissues across the course of an artery so that by pressure against the muscles the bleeding was stopped. He was much disappointed that acupressure had failed to gain a place such as he would have wished; but the introduction of the antiseptic method by Lister threw his process into the shade.

During the last year or two of his existence he found it hard to carry on his work, and he had to take more rest, but he still kept on his practice although suffering from angina pectoris. However, in February 1870 he was obliged to take to his bed, yet even then he saw patients in his sick room; later his failing strength prevented this, and he passed away on May 5, 1870.

Mr. Gordon has dealt with the facts at his disposal in an interesting manner; but as the book is one of a series connected with medicine, and as Simpson's chief claim to remembrance is associated with the introduction of chloroform, we are somewhat surprised to find that only about forty-four pages have been devoted to this portion of the subject.

We think, also, that more might have been made of Sir James Simpson's contributions to obstetrics, though no doubt the popular character of the series is responsible for the omission.

R. T. B.

PROTOPLASMIC FROTH.

The Living Substance as such, and as Organism. By Gwendolen Foulke Andrews. Pp. 176. (Boston: Ginn and Co., 1897.)

THE authoress of this wordy treatise informs us (p. 173) that she started from a neutral position with regard to Bütschli's vesicular theory, or even with a bias against it. Now, however, having become the most ardent of converts, she proceeds, with the proverbial zeal of a proselyte, to carry the original doctrine to extremes. Not content with proclaiming the existence of foams undreamt of by Bütschli—"wheels within wheels" *ad infinitum*—she utters what amounts to a denunciation of all previous statements of biological fact and theory as misleading and inadequate, and urges in effect that the whole science of life needs recasting from the new point of view. So far, she is doubtless within her rights. There is nothing in the expression of even the most singular views which can legitimately form the subject of complaint. Time tries all things; and of the numerous hypotheses that are every year thrown out to take their chance in the world of scientific opinion, some will stand the test and will become the recognised truths of a later generation, while others are simply destined to die a natural death. But there is no excuse for presenting any theory in such a form as that of the present volume. The obscurity of the style, the inordinate length of the argument, the wearisome repetitions, the general want of method and arrangement, form an unfair tax on the patience of the reader, who may be excused if he fails to find the one half-pennyworth of bread to this intolerable deal of sack. The authoress should have given us, in an orderly manner, first the facts she has observed, and secondly such interpretations of them as she thought warranted. Instead of this she has produced a confused and intricate commentary on phenomena that for the most part are either not recorded at all, or are referred to in such a vague and general manner as to make it extremely difficult to judge of their import. It is true that she appeals from time to time to her "researches" and "results," without, however, proving much more than her ignorance of the meaning of those words. Here and there we find an observation of interest, as on pages 58 (chromatin in the cytoplasm), 70 (explanation of apparent Brownian movements), 116 (protoplasmic interchange in colonies of *Raphidiophrys*). But these are scattered and scanty, nor are they recorded with scientific precision. Moreover, the want of arrangement is such that the reader who wishes to refer a second time to any observation will be at a loss to find it. Here and there, also, some semblance of a definite conclusion seems about to emerge from the general chaos. But the expected result, when not of a trite and obvious character, usually proves elusive; and the reader who had hoped to grasp a new piece of knowledge finds himself put off with a handful of empty verbiage—

> Ter frustra comprensa manus effugit imago.

If any object is discoverable, it is to show that from nature's point of view the living substance is everything and the individual organism nothing. The authoress does not seem to be aware that so far as this is true, it has occurred to previous thinkers. It is refreshing to come across a few words of common sense like the passage she quotes from Darwin on page 173. But we can assure her that the theory of natural selection not yet being dead, its "re-birth" under her auspices is at present a superfluity. On page 52 she defends her practice of saying the same thing over and over again on the ground that nature herself indulges in repetition. This is true; but nature does many other things that need not be imitated in a scientific memoir. The authoress would do well to supplement her studies from nature by taking a hint from art, especially in the way of compression. "Very few and very weary," said Macaulay of a book which had more excuse for prolixity, "are those who are in at the death of the 'Blatant Beast.'" The authoress would seem (p. 175) to be conscious that her own work may be open to the like criticism; it is a pity that she has not thought it worth while to aim at a different result.

The temptation to pass over the whole book in silence is a strong one. We have not yielded to the temptation, because we think that the authoress is capable of better things. She is apparently possessed of means, leisure, perseverance and enthusiasm—no bad equipment for a scientific career. Let her continue to observe patiently, but let her record with precision. Let her avoid cheap disparagement of the microtome and paraffin bath; they are bad masters, but may be good servants. Let her not think that she can overcome the inadequacy of figures and diagrams by abjuring their employment altogether. Let her condescend to the use of the English language as it is written by ordinary people. Above all, let her seek the advice of some leading man of science in whom she has confidence, and get him to revise her work before publication—submitting, if necessary, to a severe editing of her "results." We trust that she will take in good part what we have thought it our duty to say, for we feel convinced that if she will but consent to put a check on some of her impulses and to proceed on lines that have stood the test of time and experience, the new work with which she threatens us may yet prove to be a real and valuable contribution to the literature of protoplasm.

F. A. D.

CATALOGUE OF MADREPORARIA.

Catalogue of the Madreporarian Corals in the British Museum (Natural History). Volume iii. The Genus Montipora, the Genus Anacropora. By Henry M. Bernard, M.A. Large 4to. Pp. vii + 192. Plates xxxiv. (London: Printed by the order of the Trustees, 1897.)

OF the two genera, Montipora and Anacropora, catalogued in this volume, the latter is stated by the author to be little more than a group of specialised Montipores, so that the contents of the book may be said to relate nearly entirely to the single genus Montipora, Quoy and Gaimard. This genus is one of the reef-building, perforate corals, included with Madrepora, Turbinaria and Astræopora in the family of the Madreporidæ. It is widely distributed in the Indo-Pacific region wherever coral reefs occur, and the Museum collections of it have been largely added to of late years, by specimens obtained by Mr. Bassett-Smith, Surgeon R.N., from reefs in the China Sea, by Mr. Saville-Kent from the great Barrier Reef of Australia, by Prof. Haddon from Torres Straits, and by Mr. Stanley Gardiner from Funafuti.

The distinguishing structural feature of Montipora, as compared with the other members of the Madreporidæ, is the great development of the porous cœnenchyma between the corallites, and the comparatively reduced size and inconspicuous position of these latter. The upper surface of the cœnenchyma in these corals is furnished with an extraordinary variety of minute papillæ, tubercles, and ridges, which appear to be very liable to change, so that even in the same specimen the differences may be sufficient to constitute four or five distinct types. In spite of this fact, the author has based his systematic classification of the species mainly on the characters of this defensive surface ornamentation of the cœnenchyma, and justifies his course on the plea that there is no other available alternative. The result is that each individual specimen, and almost every fragment may, without much difficulty, be regarded as a distinct species, and in practice this is approximately the case. Thus of the eighty-eight new species constituted by the author, fifty-four are founded on single specimens or stocks, and in fourteen others, there are, in the Museum collection, but two specimens or fragments to each species. The remaining twenty new species are represented by three or more specimens each, but it is evident, with regard to most of these, that the puzzled mind of the author has led him temporarily to a wholesale lumping of the specimens. These specimens or reputed species are described with great care and detail, but that they will be accepted as valid species seems very doubtful.

The volume is illustrated by thirty collotype plates, showing the corals either of their natural size or reduced to one-half or two-thirds, and by four lithographed plates of the surface characters enlarged. Many of the collotype figures, owing to their reduced scale, are of comparatively slight value, but the enlarged figures are very carefully drawn, and should prove highly useful for comparison; they would have been of still more service if drawn on a more uniform scale, instead of, as now, ranging between six and forty diameters. We regret to note that eighteen of the *new* species in this volume are not accompanied by any figures, and of several others no enlarged surface drawings are given; it is surprising that such a deviation from the established scientific procedure of figuring new forms should be permitted in a work issued by our leading scientific institution. It would, further, have been desirable to show by figures the "middle streaming layer" and the lower and upper layers of the cœnenchyma with their bent threads, since this terminology appears to be new.

We venture to remark that the numbers of the specimens in the Museum Register are only quoted here and there in this volume of the Catalogue, whereas in the first volume they are scrupulously given in all cases. Any one who has had to hunt up a type specimen in the Museum, will acknowledge the advantage of being able to quote the "registered number," and it is very important where, as in the case of these corals, nearly every specimen is a type (and perhaps unfigured), that the registered number should be given in the published Catalogue, so as to be available for identification.

The maze of variations shown in a collection of recent corals call for the utmost patience, courage and judgment on the part of the investigator, and Mr. Bernard deserves the greatest sympathy and encouragement in the difficult and puzzling task which he has undertaken.

G. J. H.

OUR BOOK SHELF.

Das Wachstum des Menschen. By Dr. F. Daffner. Pp. vi + 129. (Leipzig: Engelmann, 1897.)

IN one hundred and thirty pages the author traces the physical development of man from the embryological state through that of fœtal existence to childhood, and thence to puberty, maturity, and decay.

The first few chapters are devoted to the proportions and weights of fœtuses of various ages, along with the causes which determine the sex of offspring. The view adopted is that the more vigorous element prevails, the argument being based upon the fact that young primiparæ (seventeen to nineteen years) bear a large percentage of boys; while women in full vigour (twenty to twenty-one years) bring forth more girls, the percentage of the latter decreasing again as the age of the mother increases.

Puberty, with its accompanying physical changes, together with a severe condemnation of the corset and modern views on beauty of the female form, occupy the next section.

The average weight of the new-born infant, the greater decrease in weight during the first few days of the male than the female, and of the first-born than the children of multiparæ, along with the subsequent daily increase, is given accurately and in an interesting and comprehensible style.

Although adopting weight *faute de mieux* as a method of comparing brains, the fact that the intellectual qualities of that organ do not vary directly with its mass is recognised, and illustrated by reference to individual cases. Unfortunately, when comparing the results of various observers, no statement is made as to which, if any, membranes are included with the nervous substance.

The book, admirably adapted for students acquainted with anthropometric methods, comprising many original observations, deals mainly with measurements and weights. The absence of instruction as to how they are obtained, detracts from its value to beginners; while the pathological and anatomical details scarcely recommend it for popular instruction.

Beschreibung der Hauptmethoden, welche bei der Bestimmung der Verbrennungswärme üblich sind. By W. Longuinine. Pp. 112, with 4 copper-plates and 21 figures. (Berlin: R. Friedländer und Sohn, 1897.)

THIS excellent work had already been printed in Russian when Berthelot's "Traité pratique de Calorimétrie chimique" appeared. The German translation may, however, be welcomed, because its scope differs considerably from that of Berthelot's book. The estimation of heat of combustion is alone dealt with by Longuinine, the rest of thermo-chemistry being left untouched. One of the results of discussing only a part of a subject is that, as far as it goes, this book is remarkably complete. Besides a full description of the calorimetric bomb and the precautions to be observed in its use, an account is given of the older methods of estimating the heat of combustion, which are still used to some extent, owing to the high price of Berthelot's bomb. Under certain conditions, duly set forth in the text, these old methods give exact results. The illustrations are capital, though unfortunately not drawn to scale, and the whole volume is handsome. By some strange mischance, it is not furnished with either an index or a table of contents.

Cheltenham as a Holiday Resort. Part I. *The Neighbouring Hill-Country.* By S. S. Buckman, F.G.S. Pp. 100. (Cheltenham: Norman, Sawyer, and Co., 1897.)

THE geology and archæology of Cheltenham and the neighbourhood are described in this book in a way which will induce the reader to make further inquiries into the why and the wherefore of the interesting characteristics referred to. The book will add to the enjoyment of ramblers in the country around Cheltenham, and will be of special value to those who visit the district in search of scientific information. The author has himself made investigations of Cotteswold geology, and his book contains the results of original observations as well as references to the work of others.

Nature's Diary. Compiled by Francis H. Allen. Eight photogravures. (London: Gay and Bird).

ON the left-hand pages are literary extracts, chiefly from Thoreau; on the right, blank paper for the events of the natural year, with here and there a printed note. The naturalist who uses the book must give it all its value. He would do much better to buy a note-book and a copy of Thoreau's "Walden." This is a book for show and not for use. The eight photographs from nature are capital.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Protective- and Pseudo-Mimicry.

I HAVE just been reading the presidential address to the Entomological Society on the subject of mimicry, and one or two statements with regard to mimicry among the *Heterocera* seem to me to stand in need of correction. It is stated on the authority of Colonel Swinhoe that *Teracolus etrida* is accurately mimicked by the geometer *Abraxas etridoides*, and that this supports his contention that the species of *Teracolus* are protected.

I described *Abraxas etridoides* from a single specimen taken on the Palni Hills, South India, by M. Elwes, pointing out its resemblance to the *Teracolus*, which also occurs in South India. This was quite enough for such an ardent student of mimicry as Colonel Swinhoe to base the above statement on, without knowing any more of the species, and probably without ever having seen it, the type being in a private collection. I have, however, lately received more specimens, and been able to learn its habits from collectors on the Palnis, where it rests in damp woods during the day on the plateau, as is the habit of the genus, whilst the *Teracolus* does not occur on the hills, but flies in the hot sun of the plains 6000 feet below; the fact being that all the species of the genus *Abraxas* secrete acrid juices and are distasteful, whilst *Teracolus* is not protected.

Again, it is stated that Danaid butterflies are mimicked by three genera of the *Chalcosia* group of *Zygænidæ*. These again secrete strong acrid juices, as does the whole family to which they belong, and they are so distasteful that hardly any other animal will touch them; their habits, too, are extremely different from those of butterflies, and no one who knows them in life could possibly believe in protective mimicry between the two groups. The *Chalcosias* sit about on tree trunks, but are very easily disturbed, when they fly with an extremely wavering flight for a short distance and then settle again. The only exception in this habit known to me is the Papilio-shaped genus *Histia*, which flies high over forest trees backwards and forwards with wavering flight, resembling that of the Vapourer Moth in our London squares, and looking so unlike butterflies that not even the veriest tyro could mistake them, besides being about one-third the size of any *Papilio*. Both these cases, therefore, will, I think, have to be relegated to the rapidly swelling ranks of museum-made mimicry.

Protective mimicry entirely depends on community of habit, and it used to be considered that accurate field observations were necessary to establish it. Now that it has been degraded to the matching of specimens in a drawer like ribbons in a shop, being a nice easy subject to philosophise on and entailing a minimum of work, it has lost all claim to serious consideration.

February 8. G. F. HAMPSON.

Oat Smut as an Artist's Pigment.

THE deep brown or sepia-coloured spore dust often seen on cereals, and arising from the presence of a fungoid growth, is sufficiently rich in colour to become useful as a pigment for the artist. The colour obtained from smutty oats, for example, is of a deep rich umber shade, sometimes approaching to sepia in tone. Satisfactory experiments were made regarding its fastness to light and atmospheric influences. Specimens of the pigment painted on paper as a water-colour were exposed to direct sunlight for several months; and after this rather severe trial, they were compared with unexposed duplicate specimens. Little change in the appearance of the colours was apparent. With mild diffused daylight—such as that of an ordinary, well-illumined room—the colour remains quite fast and unaltered. Experiments were made on a small scale with oat smut pigment, and the results seemed highly satisfactory. Several grams of the dry spore dust were collected from smutty oats, and it was found that twelve heads of such oats yielded six grams of the brownish-black dust. This powder, being of a dry and light nature, had first to be moistened with a few drops of alcohol, then mixed with gum and water to form a water-colour pigment. In its deepest tones it is of a fine sepia shade, deepening to a brown-black. On diluting with water or Chinese white, pleasing tints of a flat brown, of the pheasant-egg cast, are obtained. This colour has met with approval among artist friends to whom it was shown.

The beauty of colour and fastness to light of this pigment, from such an unpromising material, may be of interest to artists' colourmen.
DAVID PATERSON.

Leabank, Rosslyn, Midlothian.

Early Spring Flowers.

YOUR readers will doubtless have been observing how the mildness of the weather this winter, so far, has hastened on the spring flowers. I am inclined to think that some of the dates mentioned below have not often been paralleled. The dates in brackets, of the usual flowering times, have been taken from Babington's "Manual of Botany" and Johnson's "Gardeners' Dictionary." December 10, 1897, *Helleborus fœtidus* (February); December 23, 1897, *Eranthis hyemalis* (February, March); December 31, 1897, *Iris histrio* (December to March); January 14, 1898, *Mercurialis perennis*, ♂ (April and May); January 14, *Corylus avellana*, ♂; January 29, ♀ (March, April); January 15, *Galanthus nivalis* (February); January 19, *Anemone hepatica* (March, April); January 20, *Anemone fulgens* (February 20, 1897), (March, April); January 20, *Ranunculus Ficaria* (February 20, 1897), (April, May); January 20, *Viola odorata*, wild (March, April); January 21, *Iris histrioides* (March); January 21, *Tussilago Farfara* (February 20, 1897), (March, April); January 21, *Berberis Aquifolium* (April); January 22, *Potentilla Fragariastrum* (April, May); January 24, *Primula vulgaris*, wild (March to May); January 24, *Crocus aureus* (February); January 26, *Omphalodes verna* (March); January 29, *Aucuba japonica*, ♂ (June). On the ♀ plant there is no sign of flower yet, and the berries have just turned red. January 29, *Ulmus surculosa* (February 21, 1897), (March to May); January 29, *Daphne Laureola* (February, March); January 29, *Arabis albida* (February 21, 1897), (February). Among other plants which began to flower in November, and have gone on until now with unusual luxuriance, we have noted *Garrya elliptica*, ♂ (just over), *Viburnum Tinus*, *Petasites fragrans*, *Lonicera fragrantissima*, *Ionopsidium acaule*, *Erica carnea*, garden violets, and primroses, single and double, and forget-me-not. I may add that on December 1, 1897, in the course of an hour, in and around the garden here, I noted upwards of 120 different kinds of plants in flower. A few were winter flowers, but most of them were belated summer and autumn ones.

Aphides are feeding on young rose and iris leaves, and slugs are playing havoc with young shoots of herbaceous and alpine plants.

A young rabbit was seen ten days ago in Devonshire, and in Gloucestershire a nest containing eggs of the blackbird and one of the robin with eggs were found about the same time.

Dadnor, Herefordshire, January 31.
E. ARMITAGE.

Insusceptibility of Insects to Poisons.

IN your review of "Notes of a Naturalist and Antiquary" in the issue of November 18, it is said that the caterpillar of the Spurge Hawk Moth "feeds exclusively on the Sea Spurge, although the plant secretes an acrid juice 'so painfully poisonous that it is difficult to imagine a digestive apparatus competent to deal with it.'"

This recalls to me a case, which came under my notice some years ago, in which a druggist had prepared a quantity of poisoned wheat for killing sparrows, then lately introduced here and a great nuisance, by soaking it in a solution of strychnine coloured with magenta. He found that on keeping it for some time in cardboard boxes it became infested with weevils; so I examined it to find if it really contained the alkaloid. The boxes were full of weevils and their excrement, and the wheat was more than half of it eaten. Strychnine was present in the wheat in the weevils, and in apparently larger proportion in the excrement, so that it had evidently passed through the digestive apparatus unchanged.
WILL. A. DIXON.

Sydney, December 31, 1897.

MR. DIXON's letter supplies a further illustration of the curious fact that certain insect larvæ are able to feed upon poisonous plants with impunity, and can pass through their digestive system an amount of poison sufficient to kill many a more highly organised being. It is perhaps owing to their being less highly organised that they are not susceptible to the poison. Although various instances in support of the fact have been placed on record, I have not met with any attempted explanation.

M. Félix Plateau, in a paper on the phenomena of digestion in insects, published in the *Mémoires de l'Académie Royale de Belgique* (tome xli.), an abstract of which may be found in the *Annals and Magazine of Natural History* (ser. 4, vol. xvi.), has remarked that some substances resist the digestive action and are passed with the excrement—as in the case of the weevils examined by Mr. Dixon. Such, he says, are the chitine of the integuments of insects, vegetable cellulose, and chlorophyll, which by the aid of the micro-spectroscope may be detected at all parts of the alimentary tube of herbivorous insects; but he says nothing of the effects of poison.

Dr. T. R. Fraser has shown (*Ann. and Mag. Nat. Hist.*, ser. 3, vol. xiii.), that the caterpillar of *Deiopeia pulchella* feeds on the virulent poison contained in the kernel of the seed of *Physostigma venenosum*, and is unaffected by the poisonous principle of the kernel—"eserinia." Yet he ascertained by experiment that the caterpillars subjected in various ways to the action of hydrocyanic acid quickly died, proving that this species possesses no universal panacea against all poisons.

Curious to relate, another insect, a weevil *Anthonomus druparum*, feeds with impunity on the very poison which is fatal to the last-mentioned insect, namely on the kernel of *Prunus cerasus*, the poisonous properties of which depend on the hydrocyanic acid it contains. It appears, therefore, that what is one insect's food is another insect's poison, and *vice versâ*. The subject offers a fine field for investigation, and the results of further experiments, if made known, would be of interest to many besides professed entomologists.
THE REVIEWER.

Variation of Water-Level under Wind-Pressure.

IN confirmation of Mr. Wheeler's observations as to the variation of water-level under wind-pressure, two interesting beaches in the Great West Bay may be cited.

At the Chesil Bank (where all forces combine to raise the water-level) a height of 42 feet 9 inches above normal spring tide, high-water, is the height of the shingle-barrier raised by winds, waves, and currents to bar their own progress. Within the same bay, in the minor inlet of Torbay, the beach at Goodrington Sands (exposed to an easterly drift of more than 200 miles, and to waves exceeding 300 feet from crest to crest) rises 5 feet above the mark of fine weather spring tides; and this low bank is, or was when I saw it in 1889, the sole barrier between a grass field and the English Channel. The explanation clearly is that the harder it blows from the east, the more the level of the English Channel is lowered and the waters of Torbay with it.

Torquay, February 4.
A. R. HUNT.

Bipedal Lizards.

MY correspondent, Mr. H. Prestoe, has taken the trouble to examine the collections at the Natural History Museum, and by so doing has identified the bipedally-running Diamond Lizard of Trinidad, referred to in my last week's communication, with the *Ameiva surinamensis* of Gray. This identification is of additional interest, since it associates the faculty and habit of bipedal locomotion with yet a third family group of the lizard tribe, namely, that of the Teiidæ.

A good illustration of the species under notice, in a state of repose, is given in vol. v. of Lydekker's "Royal Natural History."
W. SAVILLE-KENT.

THE TOTAL ECLIPSE OF THE SUN.

THE first Indian mail dispatched after the total eclipse of January 22 has now arrived, and it brings a number of details of the work done and results obtained during the two minutes of totality. It is therefore now possible to supplement the information derived from cablegrams already published in NATURE (January 27, p. 294) with extracts from the reports of the various eclipse parties. The Government of India appears to have rendered assistance to all the observers, and it has earned the gratitude of men of science for the active interest shown in the whole of the astronomical operations. Rarely, if ever, has the work of observers been given greater facilities; and the credit for the success of the recent eclipse investigations is due, to a large extent, to the help of the Indian Government, as well as to the perfect weather which prevailed.

The invaluable aid given by the officers and crew of H.M.S. *Melpomene* was described by Sir Norman Lockyer in last week's NATURE. The results obtained by this new eclipse force appear to have exceeded the highest anticipations, and our only source of regret is that the trained perceptions of the officers and men of our ships have not previously been enlisted to advance the knowledge of solar physics by observations of solar eclipses. Naval officers are so familiar with optical instruments, that they need but a few hints to be able to make most of the observations required during eclipses. The "Melpomenes" have proved their efficiency as eclipse observers, and we hope their work will be taken as a model of what can be done upon future occasions by enlisting the sympathies of naval officers and men in astronomical investigations; for the knowledge thus obtained is both abundant and valuable. To the assistance given by Captain Batten, who took charge of all the affairs of administration and organisation, must be ascribed a large portion of the success at Viziadurg.

Sir Norman Lockyer expressed this opinion in the course of a few remarks made by him at the end of the eclipse.

"You have no right to cheer me," the *Times of India* reports him to have said, "but I have the right to cheer you, and had I a hundred and fifty throats I would do it right heartily. It is you, the officers and men of H.M.S. *Melpomene*, who have been running this camp, and we three have just stood by. You have done all the work, and you have been making a bit of history, not only for British science but for the British Navy. The records of this expedition will be logged in one of the Admiralty books, and I am proud to have been associated with you in this Eclipse Expedition of 1898. The work you have done has not only been in proportion to your numbers, a hundred and fifty to three, but you have borne the burden and heat of the day, and I thank you from the bottom of my heart for the admirable manner in which you have behaved towards we land-lubbers. We have done our best, you have done your best, and between us we have to-day accomplished what has never previously been done in the history of the world. A hundred and fifty British Bluejackets have observed an eclipse just as perfectly as if they had been drilled for years instead of a few days. We have been perfectly successful along all the lines of work we laid down, and we have done everything we tried to do. I do not really thank you a bit, but I congratulate you from the bottom of my heart upon the splendid success you have achieved."

From the various reports which have now reached this country, we make a few extracts to show what scientific results were obtained at the eclipse stations, beginning with extracts from the letter contributed by Sir Norman Lockyer to Tuesday's *Morning Post*.

Viziadurg.

"When I come to the scientific results I hardly know how to begin, for there is so much to tell. The 'Melpomenes' have certainly beggared all former records. In the prismatic cameras every plate we hoped to expose at the different times, carefully thought out beforehand and bearing in mind the capacities of the two instruments, now bears a precious record. In the two cameras the number of spectra photographed amounts to about sixty; of these forty are distributed over four plates—'dropping plates,' as they have been called, because they drop inch by inch and second by second at the beginning and the end of the total phase. On each plate therefore we get a history of the visible solar atmosphere for ten seconds; the lengths of the arcs tell how the different chemical constituents are distributed, and their positions tell us exactly what the constituents are. In some of these records it has been roughly estimated that we have to deal with a thousand lines. It is pretty certain, then, that many months of careful measurements will be necessary before we can form a detailed idea of the advance secured.

"As was anticipated, the increased dispersion has distinctly helped us on in our knowledge of the corona. Several beautiful corona images have been secured on both of the prismatic cameras. The want of any visible connection between the materials of the corona and of the chromosphere is again demonstrated. The definition in some of the plates is so good that the bases of the streamers are depicted in the coronal rings, while the prominence and chromosphere rings take no notice of them whatever. This result seems entirely in harmony with the telescopic observations of the structure of the corona which I made with a 3¾-inch Cooke telescope. The prominences seemed entirely disconnected from the corona structure lying near them, and there was no increase of luminosity as the prominences were approached."

The "flash" spectrum was photographed, both at the beginning and end of totality, with the six-inch and nine-inch prismatic cameras. The results of the six-inch camera with the two prisms (see p. 295) surpass all previous records, about double the number of lines photographed in Novaya Zemlya in 1896 being recorded upon the plates. Photographs of the corona were obtained with a four-inch telescope fed by a cœlostat. Lieut. Blackett, R.N., in charge of the star observations, reported the appearance of some object between Mars and Jupiter, where no star down to the third magnitude occurs on the chart. Prof. Pedler, using a grating spectroscope, observed during the total phase "that the strong arc lines of iron and magnesium were visible on the inner corona, while no spark lines were seen."

Meteorological Phenomena.

Mr. J. Eliot, F.R.S., the Meteorological Reporter to the Government of India, says:—

"The meteorological phenomena accompanying the eclipse were much less striking than was anticipated. Observations expressive of the air were taken with a barometer and a Richard Frère's continuous self registering barograph. The trace on the barograph on the 22nd was practically identical with those on the 21st and 23rd, and the influence of the solar eclipse was either nil or very small, and will require careful examination of the traces to detect.

"Observations of the temperature of the air were taken by means of six thermometers by Bailey, which had been carefully tested at Kew, and also by means of a Richard Frère's thermograph. The observations show that temperature rose more slowly than usual from 11 a.m. until about totality, when it fell rapidly about 5° F., and was constant for some time after totality.

"This fall in temperature at Viziadurg was partly at first due to the usual change from land winds to sea breezes, which usually takes place at noon. On the day of the eclipse easterly winds prevailed during the previous night and morning until about 12.15 p.m. A short period of calms and light airs obtained until three minutes before totality, when the wind shifted to west, and blew more or less steadily and strongly during the remainder of the day. The only instrument which showed any large influence due to the eclipse was the solar radiation thermometer. It rose steadily from sunrise until about 5 minutes after the commencement (*i.e.* 11.15 a.m.), when it read 144° F. It fell continuously and with increasing rapidity until the end of totality, when it registered 81½° (practically the temperature of the air.) During the latter part of this period it fell at the rate of upwards of 4° in five minutes."

Sahdol.

The observations at Sahdol (says the *Pioneer* of January 25) were completely successful. The Astronomer Royal exposed seven large plates during totality, and twenty four more during the partial phases. His photographs show the sun's image four inches in diameter. Prof. Turner took twelve pictures during totality, and two plates in polarised light. The photographs taken by the Astronomer Royal and Prof. Turner during the eclipse have been developed, and are highly successful.

Mr. Mitchie-Smith, the Madras Government Astronomer, took seven good photographs with a 20-foot telescope. Photographs of the coronal spectrum were taken by Mr. Moos. Several draughtsmen of recognised ability, including General Strahan, Sir Thomas Holdich, General Woodthorpe, and Colonel Barr, made coronal drawings during totality.

Wardhaganj.

The eclipse was observed here perfectly. Twelve photographs of the corona were secured and twenty-four photographs of the spectrum. All the photographs developed are very good.

Captain Hills' corona spectra are excellent, showing a small radial extension of the lines. Captain Hills obtained a series of exposures for the flash at the beginning and end of totality, showing the whole spectroscopic history of the sun's limb, from the solar spectrum through the flash to the prominence.

Mr. Newall found the coronal spectrum too faint at a quarter diameter from the sun's limb for determination of the velocity in the line of sight, but caught the bright lines in the spectrum on another photograph at the end of totality. Mr. Newall observed very strong polarisation in the corona visually, and also observed the green coronal ring with the objective grating spectroscope.

JEUR.

The eclipse party from the Poona College of Science, under Prof. K. D. Naegamvala, had its camp at Jeur, and within two hundred yards of it were the Lick observers, under Prof W. W. Campbell. At Jeur were also the Japanese astronomers, under the direction of Prof. Taero, with Prof. Hiramaya and two assistants. Two miles further south was Mr. C. Burckhalter, with Major Harkness, Captain Dugon, and others. Every branch of eclipse work was represented at Jeur.

All the eclipse parties at this station may well be congratulated on the successful issue of their arduous labours and careful preparation. Thirty good photographs of spectra, fifteen of which are excellent, were secured by Prof. Naegamvala, and about the same number by Prof. Campbell. In the case of the Poona eclipse party these preparations were rendered particularly arduous by the very late arrival of some of the principal instruments sent out from England; Prof. Naegamvala's Cooke 6-inch spectroscope having only arrived on January 11. Upon this instrument two prisms of 45° were mounted, and the length of spectrum given by them was twelve inches. The "flash" spectrum was caught on three plates, and on one spectrum the length from D_3 to H is eight inches. The Maharajah of Kohlapore, who had liberally supported Prof. Naegamvala with funds for the eclipse instruments, specially deputed Prof. Apte to join the Poona party Prof. Apte secured some very interesting observations on the visibility of planets during the course of the phenomenon, and they will be of value in determining the intensity of the corona light.

In addition to the information given in the foregoing extracts, we learn that at the British Astronomical Association's camp at Talni good photographs of the corona were obtained, and Mr. Evershed succeeded in photographing the "flash" spectrum, and in carrying out the whole of his extensive spectroscopic programme. At Gogra, north of Nagpur, Dr. Copeland obtained photographs of the corona with his telescope of 40 feet focal length. Particulars of the instruments employed at the various stations have already been given in NATURE.

PITCHER-PLANTS.[1]

AMONG recent additions to the attractions of Kew Gardens is a house largely devoted to pitcher-plants; and the past year has seen several important additions to our knowledge of this very interesting class of plants.

Pitcher-plants, as enumerated by Prof. Vines, are found in ten genera, distributed through five widely separated natural orders, viz. (1) Sarraceniaceæ (*Sarracenia*, *Darlingtonia*, *Heliamphora*); (2) Nepenthaceæ (*Nepenthes*); (3) Asclepiadaceæ (*Dischidia*); (4) Saxifragaceæ (*Cephalotus*); (5) Lentibulariaceæ (*Utricularia*, *Genlisea*, *Polypompholyx*, *Biovularia*). Of these the only natives of this country are the "Bladder-worts" (*Utricularia*), of which several species are not uncommon in running and standing water. But the genus with which the name is usually associated is *Nepenthes*, the only representative of the order, to which about thirty-two species are assigned by Bentham and Hooker, natives of the East Indian Archipelago, or scattered through Asia, Africa, Madagascar, and Australia;[2] but the number of known species is now considerably larger. About forty species or hybrids are now under cultivation at Kew. Mr. H. J. Veitch—whose firm has done so much for the introduction of these plants into cultivation—in his admirable account of the genus in the *Journal* of the Royal Horticultural Society, gives twenty-four as the actual number of true species in cultivation, in addition to a large number of varieties, and primary, secondary, or tertiary hybrids.

Nepenthes is not grown for the sake of its blossom. The flowers, borne in terminal inflorescences, are small, and of simple type, the perianth consisting of four usually green segments. They are unisexual and diœcious. I find no reference to any insect-visitors to the flowers; and they are probably anemophilous. The interest of these plants centres in the remarkable terminal appendages to the leaves in all the known species, the ascidia or pitchers, which are constructed on a uniform general type, though varying greatly in size, form, and colour. To promote the formation of these pitchers, cultivators usually "stop" the blossoming, so that special cultivation is needed for the production of hybrids. The pitcher itself is generally regarded as an expansion of the petiole or leaf-stalk; Sir Joseph Hooker describes it as a "modification of a gland situated at the apex of the midrib of the leaf." The lid is always completely closed until maturity, and the fluid is excreted within the enclosed chamber.

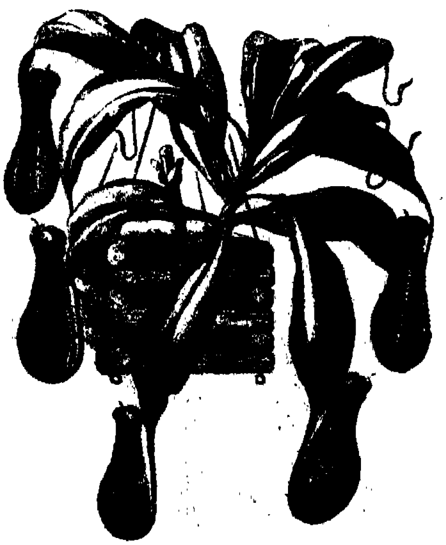

FIG. 1.—*Nepenthes Sedenii*, one-sixth natural size.

The composition and properties of this fluid have been the subject of many investigations. Notwithstanding that one or two recent inquirers have come to a contrary conclusion, the observations and experiments of Prof. Vines may be said to have finally settled the point that it contains a true digestive principle. The teleological bias of the eighteenth century connected these pitchers of water with the needs of thirsty travellers or of birds. Linnæus describes the pitchers as "aquam dulcem limpidam, amabilem, confortantem, frigidam suppeditantia, ad necessarium hominis usum," and goes into raptures when adopting the name *Nepenthes* proposed by Breyne:—"Cum enim et haec non Helenæ Nepenthes, certe Botanicis omnibus erit. Quis Botanicorum longissimo itinere profectus, si mirabilem hanc plantam reperiret, non admiratione raperetur, totus attonitus, praeteritorum malorum oblitus, mirificam Creatoris manum dum obstupescens adspiciret?" There are unfortunately two valid arguments against Linnæus's theory:—In the first place the fluid is absolutely unpotable; and secondly, nearly all the known species of *Nepenthes* grow in climates where the traveller need never be thirsty. Mr. Burbidge states that on the great mountain range of Kina Balou, in North-west Borneo, the "paradise of pitcher-plants," there is a deluge of rain every night in the year, while in the day-time the air is in a constant state of "Scotch mist." The internal surface of the pitcher is provided with a large number of specialised glands, from which the secretion is poured out into the pitcher. The fluid has a slightly acid reaction, and yields a large quantity of solid matter on evaporation; and the most trustworthy analyses that have been made show that the preponderating unorganised constituents are potassium chloride and malic and citric acids, with smaller quantities of soda, lime, and magnesia. The researches of Vines have convinced him that the pitcher secretes an enzyme which has the property of digesting organic substances in the presence of an acid which is always found in the fluid; and that this digestion is not due to the putrefactive bacteria which are always present in the liquid. All the species of *Nepenthes* are either epiphytic or grow in wet soil, and agree with other carnivorous plants, such as *Drosera* and *Dionæa*, in having a very reduced root-system; the food-substances obtained through the pitchers thus supplying the lack of nutriment from the soil.

[2] Mr. Bailey describes and figures two new species from Queensland.

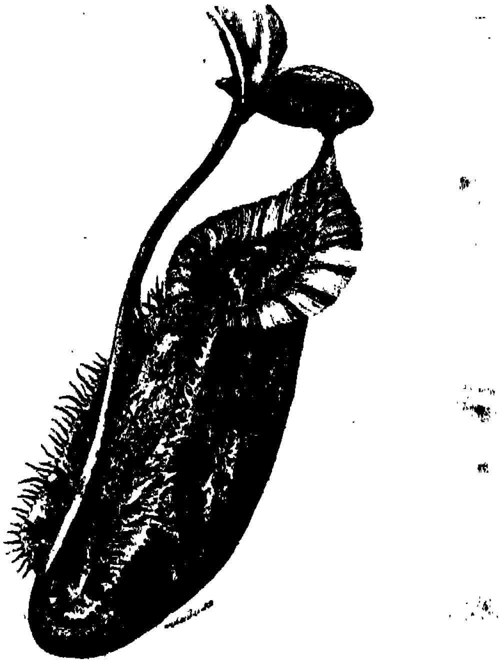

FIG. 2.—Pitcher of *Nepenthes Dicksoniana*, one-fourth natural size.

None of the other pitcher-plants, with the possible exception of *Cephalotus*, are, according to Vines, truly carnivorous. In most cases they are insect-traps, but they produce no digestive enzyme; the captured insects are decomposed by the microbes which abound in the fluid, and the products of decomposition absorbed by the plant. In *Darlingtonia*, and in *Sarracenia*, one species of which, the "Side-saddle-plant," is abundant in bogs in the Northern United States and in Canada, the lid is replaced by a hood, and insects are attracted by honey-glands placed near the mouth of the pitcher. In *Dischidia* the pitcher, which has no lid, is not nutritive; its main use appears to be to husband the water required by the plant. The pitchers of *Cephalotus* closely resemble in appearance those of *Nepenthes*. Several species of *Utricularia*, or Bladder-wort, are among the prettiest of our water-plants, with their pale yellow flowers and much-divided leaves, ornamented with the minute bladders, which are closed by a valve opening inwards, thus preventing the escape of innumerable aquatic animals which creep into them. It may be added in conclusion that one of our few native non-chlorophyllous root-parasites, the Tooth-wort (*Lathræa squamaria*), belonging to the Scrophulariaceæ, has singular hollow underground scale-leaves, which may be regarded as rudimentary pitchers, and resemble those on the exotic terrestrial species of *Utricularia*. Their purpose appears to be the reverse one to that of the pitchers of *Dischidia*, viz. to serve as organs for the excretion of superfluous moisture.

Our illustrations are taken from Mr. Veitch's paper on *Nepenthes* in the *Journal* of the Royal Horticultural Society. Fig. 1, a hybrid known as *N. Sedenii*, a cross between *N. Khasiana* and an unknown species, shows the general habit of the genus. Fig. 2 represents the magnificent pitcher of *N. Dicksoniana*, a cross between *N. Rafflesiana* and *N. Veitchii*. In Fig. 3, *N. Edwardsiana*, Hook. f., a spike of male flowers is shown; also a magnified portion of the glanduliferous surface of the pitcher.

A. W. B.

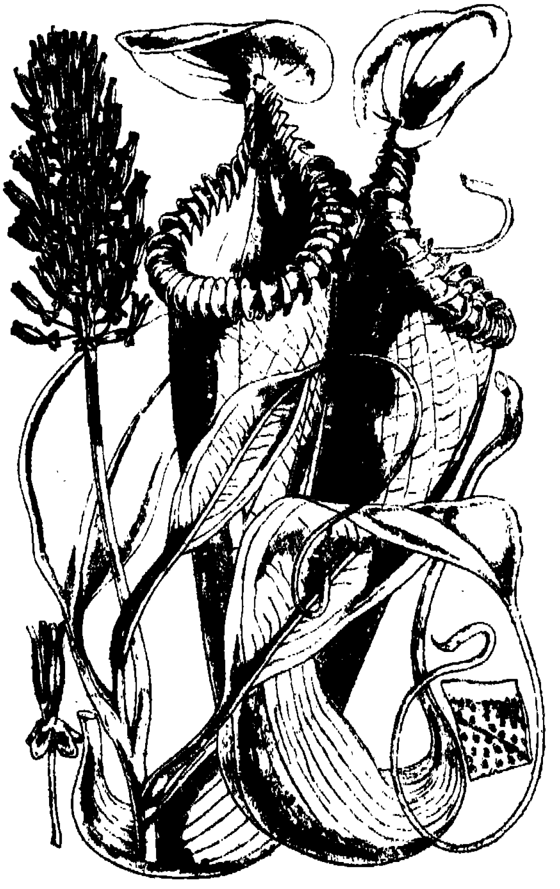

FIG. 3.—*Nepenthes Edwardsiana*.

A NEW ARTILLERY CHRONOGRAPH.[1]

THE ordinary chronograph used in artillery experiments consists of a falling shutter held suspended by an electromagnet whose circuit is broken by the projectile, which cuts a wire in its passage. Other wires are cut at intervals along the path of the projectile, and as each one is cut a knife is liberated which strikes the shutter and imprints a mark upon it. These marks form a record of the speed of the ball in terms of the known speed of a falling body.

---

[1] Based upon an article in *La Nature*, pp. 97 and 122, 1898.

This apparatus, which has been perfected by many devices, is open to a fundamental objection. The release of the shutter and of the knife takes time, a short time may be, but an amount of time which becomes objectionable when intervals as small as one-twentieth of a second have to be dealt with. Projectiles nowadays attain velocities of half a mile per second, and a new and more accurate means is required for dealing with them.

Such an instrument has been devised by Prof. Cushing Crehore, of Dartmouth College, and Mr. Owen Squier, lieutenant of artillery in the United States Army. It is based upon an electro-optical principle of comparatively recent discovery, that known as the Faraday effect. When a beam of light is polarised by a Nicol prism and then sent through another Nicol prism, it is transmitted if the polarisation planes of the two prisms are parallel, but is totally extinguished if the planes are crossed. If, however, a tube containing carbon bisulphide or other rotatory substances is interposed between the crossed Nicols, the light reappears as soon as the tube is exposed to a strong magnetic field. This magnetic field is produced by a coil of wire surrounding the tube, and hence it will be seen at once that an electrical contrivance is possible which interrupts or restores the beam of light. Add a photographic recording apparatus, and the scheme underlying the Crehore-Squier arrangement is complete.

The recording apparatus is shown in Fig. 1. P is the polarising Nicol, A the analyser, T the tube containing the carbon bisulphide and surrounded by the magnetising coil. W is the camera containing the revolving sensitive plate driven by the small motor *m*. The camera is provided with a falling shutter which covers a thin brass disc provided with two small openings. One of these openings admits the polarised light. The other admits light which has had to pass through a hole in a piece of aluminium foil carried on the prong of the vibrating tuning-fork shown in the figure. The vibrations interrupt and restore the light at perfectly constant known intervals, and make a record of dots on the plate, which serve to determine the time for the projectile record. The falling shutter serves to limit the exposure to a portion of one revolution of the plate, and to prevent the superposition of records.

The projectile, in starting from the mouth of the cannon, breaks the first wire and the magnetising circuit, thus extinguishing the light. When it reaches the second wire, it restores the circuit in a manner explained by No. 2 (Fig. 1). B and B′ are terminals of the circuit, A is an insulating piece, and C C are elastic metallic plates kept apart by the insulated wire D. The projectile in its passage whips out the wire D, and allows C C to touch and establish the circuit. The next wire breaks it again, the next restores it, and so on. In the figure, four circuits are indicated, which may be brought into play one after the other, thus providing for the measurement of eight time intervals. By placing these wires at suitable distances from the cannon's mouth, any portion of the path may be minutely investigated.

The most striking information derived from such measurements is that the speed of the projectile goes on increasing for some time after it has left the cannon's mouth. Starting with a muzzle velocity of about 480 m. per second, the projectile increases its speed to, say, 515 m. per second in traversing the first 6 feet from the mouth. It is only after having travelled some 25 yards that the projectile is reduced to its original muzzle velocity. This proves that the impulse of the expanding gas is felt some distance along the path of the projectile.

By a modification of the arrangement described, the inventors have also succeeded in determining the speed of the projectile inside the barrel of the gun. For this purpose they secured a wooden lath to the cone of the projectile (Fig. 2), provided with rings of metal at decreasing intervals. These rings were connected among themselves and to the projectile by a wire running along the length of the rod, the whole being smoothed and turned into an accurate cylindrical shape. A wooden block, A (Fig 3), was fastened on the muzzle of the gun by means of screw clamps, and a brass collar with steel rings, C, was made to embrace the rod, which in the original position of the projectile just projected from the muzzle.

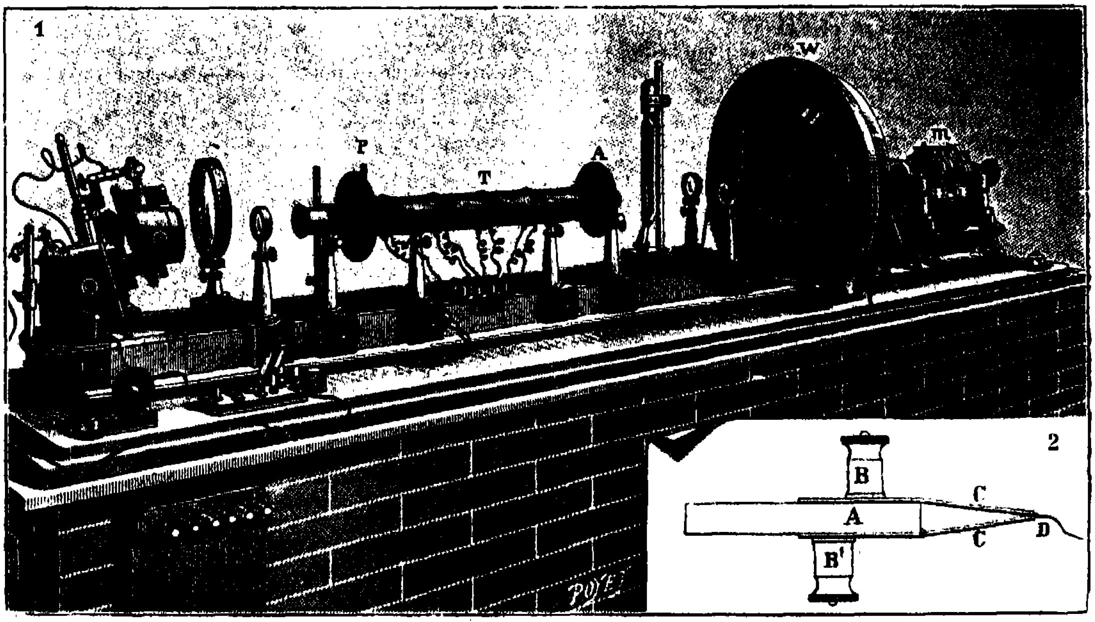

FIG. 1.—Recording apparatus. T tube containing carbon bisulphide surrounded by magnetising coils. W camera. No 2, arrangement for closing circuit.

A circuit through the steel rings, the brass collar, the metallic rings on the rod, the projectile and the body of the gun was completed whenever the brass collar touched one of the rings on the rod. It was broken when the wooden portions passed, and so an alternate transmission and extinction of the polarised beam was brought about, which served the same purpose as in the arrangement first described. The curves obtained showed a constant acceleration of the projectile within the barrel, which would indicate a constant pressure of the gas. But unfortunately no complete records were obtained, the rods having broken off half-way through the barrel.

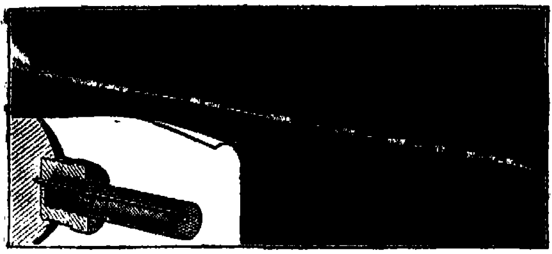

FIG. 2.—Apparatus for measuring velocity of projectile inside the barrel.

The most remarkable circumstance of all these trials lies in the extreme smallness of the intervals measured. In some experiments ten points were taken along a length of 72 cm., which corresponds to a duration of 0·005 seconds, and reduces the interval observed to 0·0005 seconds.

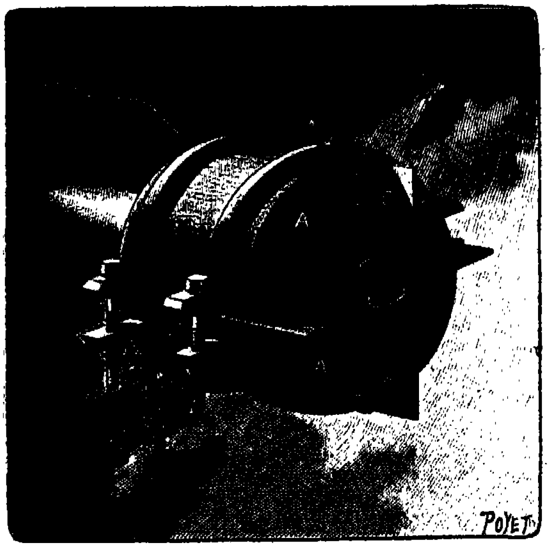

FIG. 3.—Block attached to muzzle for making circuit.

Needless to say, the apparatus may with equal success be applied to other fields of micro-chronographic investigation.

NOTES.

At the meeting of the Royal Society next Thursday, February 24, for the discussion of the scientific advantages of an Antarctic expedition, the following are likely to take part in the discussion which will be opened by Dr. John Murray:—The Duke of Argyll, Sir Clements Markham, Sir Joseph Hooker, Sir Archibald Geikie, Dr. Neumayer (Director of the Deutsche Seewarte), Dr. Sclater (Secretary of the Zoological Society), Prof. D'Arcy Thompson, and others.

PROF. ALEXANDER AGASSIZ writes to Prof. Ray Lankester from Sura, Fiji, under date January 3, as follows: "I got here first days in November, and found my steamer awaiting me; started the day after reaching Sura, and have been on the full run ever since. I have learned more about coral reefs than on all my former expeditions. Naturally my experience elsewhere has been of great service. The problem is getting more and more complicated. My boring was a fizzle. I only got to 80 feet; but in a region where there are elevated reefs nearly 1000 feet thick, that means nothing. From all I hear about the Funafuti boring (700 feet), and from what Prof. David writes, I fancy the bore-core will not bring us any nearer to a conclusion. It certainly can not help us to ascertain how atolls have been formed."

THAT until a few days ago (February 10) there lived in Eaton Square a nephew of Sir John Moore, and a man who many years ago attained a considerable distinction in geology, was little known to the present generation of scientific workers. John Carrick Moore was born in 1804, and inherited an estate in the northern part of The Rhinns of Wigtownshire, near Stranraer. He became a Fellow of the Geological Society in 1838, and two years later read a paper on the rocks which form the west shore of the bay of Loch Ryan, at the head of which Stranraer is situated. In subsequent years he devoted much attention to the fossiliferous Silurian strata of Wigtownshire and Ayrshire, and contributed the earliest account of the rocks near Carrick. He likewise published accounts of the Tertiary fossils of St. Domingo and Jamaica. For many years he served on the Council of the Geological Society, terminating his official connection in 1875. In 1846 he was appointed one of the Honorary Secretaries, and later on for several years he was a Vice-President of the same Society. He was elected a Fellow of the Royal Society in 1856. Educated at Queen's College, Cambridge, he early gained a sound knowledge of mathematics and physics, and in after years he contributed a few articles to the *Philosophical Magazine*, dealing with the influence of the obliquity of the ecliptic on climate, and criticising some of the principles enunciated by Ramsay with regard to the erosion of lake basins. Living to the advanced age of over ninety-four, Moore long outlived the majority of his old friends, of whom Murchison was one with whom he was intimately associated.

WE have received further correspondence relating to the two Societies in Lincolnshire, to which reference was made in our issues of December 30 and February 3. It appears that the older Society, the Lincolnshire Naturalists' Union, does not regard with unmixed friendliness the newer and possibly more vigorous Science Society. Into this unfortunate conflict of interests it is not our province to enter, and we can only repeat with renewed emphasis that it is a most serious mistake to allow the spirit of rivalry to enter into the matter at all. The welfare of both Societies can only suffer, and the progress of science in the county can only be retarded by friction. The Lincolnshire Science Society explains its origin by accusing the Union of failing to carry out the objects for which it was founded. There may or may not be truth in the accusation, but we are bound to admit that evidence of scientific activity on the part of the Union has not been obtainable. We cannot find the latter body among the corresponding societies of the British Association; neither can we learn that any publication has been issued under its auspices. Attention may be called to an article by Prof. Meldola, on the work of local societies, published in these columns in 1896 (vol. liv. p. 114), in which some of the causes of the decay of such societies are pointed out, and the advantages of federation insisted upon. We can only hope that Lincolnshire will not present to the scientific world a divided front on a question in which both parties are really striving for the same end.

IT is announced that in connection with the completion of his twenty-fifth year of office as Woodwardian Professor of Geology at Cambridge, Prof. T. M'Kenny Hughes, F.R.S., is to be the recipient of an illuminated address, to be presented at a public dinner to be held in London on Saturday, the 26th inst. Sir Archibald Geikie has consented to preside.

THE death is announced of Dr. Rudolf Leuckart, professor of zoology and zootomy at Leipzig.

PROF. ALEXANDER GRAHAM BELL has been elected president of the National Geographic Society, Washington.

MANY men of science will grieve to learn that there is no improvement in the condition of Sir Richard Quain, who has been in ill-health for some time, and is gradually getting weaker.

WE regret to see the report that Sir William Dawson, C.M.G., F.R.S., formerly principal and vice-chancellor of the M'Gill University, Montreal, has had a stroke of paralysis.

DR. NANSEN has consented to deliver a lecture at the Queen's Hall on the evening of Monday next, February 21. Lord Lister will take the chair.

The organisation of the Corps of Electrical Engineers, Royal Engineers (Volunteers), has now been completed, and applications for membership may be made to the adjutant, Captain Brady, R.E., at the headquarters of the Corps, 13 Victoria Street, S.W. Major J. Hopkinson, F.R.S., is in command, and Lord Kelvin is honorary colonel. The War Office is offering every encouragement to the development of this new Corps of Volunteers.

IN the House of Commons on Monday, Sir H. Vincent asked the Under-Secretary of State for Foreign Affairs what grant would be proposed from public funds for the representation of the United Kingdom at the Paris Exhibition of 1900; and if he could state what sums Germany, the United States, and Italy proposed to allocate for the representation of their national industries. In reply Mr. Curzon said:—It is proposed to ask Parliament for a grant of 75,000*l.* to provide for the expenses connected with the British section. The German Government has sanctioned a grant-in-aid of 5 million marks, or about 250,000*l.* The United States Government has made a Treasury estimate of 350,000 dollars, or about 70,000*l.* In Italy nothing has yet been officially settled as to the exact amount to be devoted to this purpose.

A GREAT authority on iron and steel has passed away in the person of Prof. Styffe, who died in Stockholm on February 3, having just entered his seventy-fifth year. After completing his studies at the University of Upsala (says *Engineering*) he passed through the School of Mines at Falun, and was afterwards engaged as a mining engineer in the Sala silver mines, but he was soon called by his Government to be the chief director of the Royal Technical Institution at Stockholm. Here he rendered great services during more than a quarter of a century, and was consulted at the same time by the Board of Iron and Steel Works (Jernkontor) in Sweden. When the construction of railways was begun in Sweden, some forty years ago, the question naturally arose of using the excellent native iron and steel for the railway plant, and the State appointed a Committee to make careful researches as to its adaptability for the purpose. Director Styffe was appointed chief of this Committee, and carried out these researches during a period of five years in the most minute and scientific manner. His results were published in the *Annals* of the Jernkontor, or Board of Iron and Steel Works in Sweden. They were translated into English by C. P. Sandberg, and published under the title of "The Elasticity, Extensibility, and Tensile Strength of Iron and Steel." The work caused a great deal of interest in the engineering press at the time. Styffe was juror for Sweden for mining and metallurgy at the London International Exhibition in 1862, and at the subsequent exhibitions in Paris and Vienna. Last summer he was present as an honorary member of the International Congress for the Testing of Materials at Stockholm, and was duly honoured for his long and valuable services.

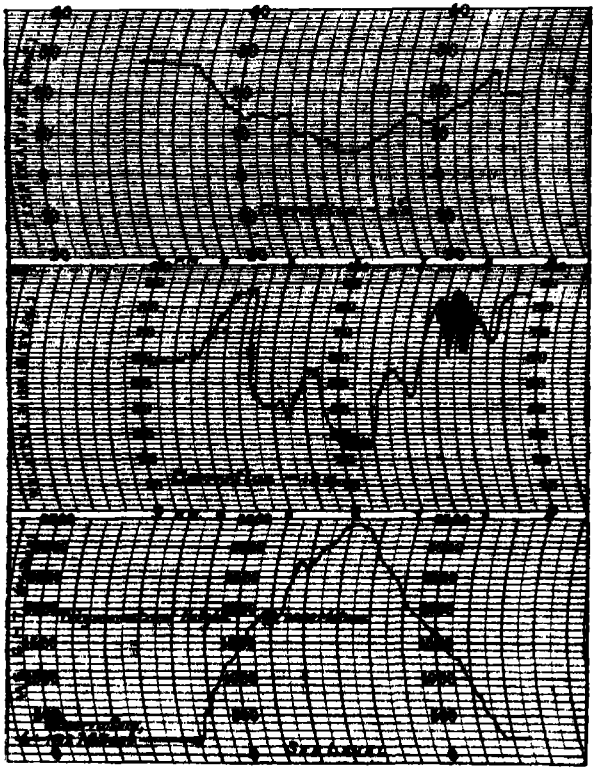
AMERICAN geographers appear to be far from pleased with the projected plans of Captain Sverdrup. He purposes this summer to use the *Fram*, with Dr. Nansen's approval, for the exploration of the northern shores of Greenland. These plans, it is objected, materially affect and invade Lieut. Peary's field of work, who has not only already done a great deal on the north coast of Greenland, but has for a long time had in view a project for its continued exploration this summer. The American Geographical Society, in its recently-issued quarterly *Bulletin*, publishes two strong protests. It is asserted that Captain Sverdrup, by setting out at the same time, adopting Peary's route and aims, utilising his experience, and interfering with his resources of men and dogs in North Greenland, will frustrate the labour of ten years, and turn to advantage all that skill and courage has already accomplished. The caustic comment is made: "There is no legal impediment in Captain Sverdrup's way. He can do these things if he will, and men will remember him as the one Arctic voyager whom they would gladly forget."

THE "Year-Book" of the Royal Society, No. 2, 1897–98, has just appeared. There are several features in it which lend additional interest, and form an improvement on the last issue. For instance, the scheme of regulations for the administration of the Publication Grant of 1000*l.* from H.M. Treasury is given, as well as a good deal of information regarding the annual Government Grant for scientific research, such as an account of the appropriations, and a list of the Boards recommending assignments from the fund. A note on p. 1 states that applications for grants, and the reports on them, must be sent in by January 31; but the late issue of this "Year-Book" (apparently it is brought down to November 30, in each year) renders the information valueless, at any rate for the current year. The President's address and other anniversary matter is now omitted from the *Proceedings*, and published instead in the "Year-Book."

A STRIKING novelty in vacuum tubes is described by Prof. Trowbridge and Mr. Burbank in the February number of the *Philosophical Magazine*. The space between anode and kathode is done away with, and a continuous wire is led through the exhausted tube, which is then inserted in a circuit containing a spark gap and one of Trowbridge's improved "rheostatic machines." The latter is charged by means of a battery of 10,000 storage cells. The condensers constituting the machine are charged in parallel, and then discharged in series, thus giving rise to a voltage which may be made to approach a million. It is not surprising that by this means novel results are obtained. The tubes glow all over with a brilliant phosphorescence. X-rays are developed; but their photographic effect cannot well be brought into evidence, owing to the fact that brush discharges pass between the tube and the sensitive plate, which on development has a star-spangled appearance. The skin of the hand shows all the symptoms of X-ray burning. An aluminium mirror attached to the wire inside the tube throws a beam of kathode rays upon the wall, which may be deflected by a piece of tinfoil. At extreme exhaustions no difference is noticeable whether the tube is on the anode or the kathode side of the spark gap. The distinction between anode and kathode rays disappears.

FROM the Blue Hill Meteorological Observatory, of which Mr. A. Lawrence Rotch is director, we have received a *Bulletin* (the first issued from the Observatory), by Mr. S. P. Fergusson, on the highest kite ascensions in 1897. On September 19, 1897, as already described in NATURE (vol. lvi. p. 540), the meteorograph was raised to a height of 3013 metres above sea-level. The highest kite was 40 metres above the meteorograph, or 3052 metres above sea-level. The kites and meteorograph were sent up from near the summit of the hill, which is 192 metres above sea-level. On October 15, 1897, the meteorograph was raised to a height of 3571 metres above sea-level, or 558 metres higher than on September 19. The highest kite was 40 metres above the instrument, or 3611 metres above sea-level. At the top of the line were a Lamson ribbed kite with curved surfaces, having an area of 6·60 square metres, and a self-adjusting Hargrave kite, having an area of 3·35 square metres. Two other Hargrave kites, each having an area of 2·13 square metres, were respectively attached at distances of 2000 and 3500 metres from the top of the line. The length of line employed was 6300 metres, and the pull, when all the line was in the air, varied between 56 and 68 kilograms. The instrument left the ground at 3.48 p.m., and reached the highest point at 6 p.m. The work of reeling in the line began at 6 p.m., and the instrument reached the ground again at 8.20 p.m. The meteorogram obtained during this flight is one of the best that has been secured, being complete, with very clear and smooth lines. It is here reproduced from the *Bulletin*. At the highest point reached the temperature was 5·0° C., and at the Observatory it was 22·2°. An interesting feature of this flight was the passing of the meteorograph through the cumulus and alto-cumulus levels of clouds, as shown by the increase followed by a decrease of humidity at heights of 1500 and 2800 metres. At the Observatory the wind was from the south-west during the entire flight, and the velocity varied between 5·4 and 8·0 metres per second, true velocity. Above the height of 1000 metres the direction of the wind was north-west.

KITE METEOROGRAM OF OCT. 15, 1897.



PROF. GEORGE M. STRATTON, of the University of California, has made a novel experiment in inverted vision by wearing for eight days a mask fitted with lenses which invert the visual image, thus projecting it upon the retina in an erect instead of the normal inverted position. He soon learned to refer all objects to their correct positions, in other words to see them right side up; but, on removing the apparatus at the expiration of eight days, everything appeared to be upside down at first. He therefore concludes that the seeing of objects right side up is due to a mental rectification of the visual image actually projected upon the retina.

AT the meeting of the New York Academy of Sciences on January 24, Mr. E. L. Thorndike, of Columbia University, gave an account of a long series of interesting experiments on comparative psychology. These experiments were made upon cats, chickens, dogs, monkeys and other animals, and were supplemented by the experience of professional animal trainers. According to a report in *Science*, cats were placed in boxes with doors so arranged that they could be opened from the inside in various ways, in one set of experiments by pressing a latch, in another by pulling a cord, by pulling a hook attached to a cord, or by turning a button. Again the arrangement was more complicated, and two or three separate movements had to be combined in order to release the door and let the animal out to reach the fish placed outside the cage. Curves were given showing the rate at which the kittens learned the various tricks, the time taken to get out becoming gradually shorter. The trick was always learned by accident; one lucky hit would prepare the way for another. There was no trace of rational inference. Seeing another animal do the trick a hundred times was no help. Nor was it possible to teach the trick by taking the kitten's paw and putting it on the latch, and so opening the door, no matter how often it was repeated. A habit once formed artificially will overpower natural instincts. A chicken that had been compelled to jump from a box to the floor in a roundabout way by a cardboard placed in its way, felt unable to jump down to its food directly when the card was taken away.

SIR A. HARDINGE's report on the East Africa Protectorate, 1897 (c.-8683), contains a careful summary of the manners and habits of the native tribes. There are many broken or slave tribes, besides full tribes. One common characteristic appears to be the looseness of the tribal tie and the small amount of direct government, either by chief or council. The Wagiriama of the Malindi district are a vigorous and handsome race of a dark brown, almost black, colour; and closely allied to them, though politically distinct, are the Wakauma. They have a loose republican sort of organisation, based partly on tribal subdivisions and partly on a kind of freemasonry known as "kambi," which involves several degrees, each attended by its special ceremony of initiation. The Wapokomo of the Tana River district are a fairly handsome and intelligent Bantu race, dwelling in thick clusters of beehive-shaped straw huts all along both sides of the river. The Wakamba occupy the Attri district, and a very useful table is given of the internal subdivisions so far as they are known. Each family occupies its own "boma" or hamlet, and a man on marrying usually forms a boma of his own, consisting at first, perhaps, only of his own hut, but gradually expanding into a hamlet and thence into a village, of which its founder is regarded as the chief. Here is Sir Henry Maine's famous patriarchal family in the making; but we should much like to have further particulars and assurance that this description is justified by accurate scientific observation. The tribes of the interior have neither idols, priests, nor temples; but there is a vague general belief in spirits, mostly evil, dwelling in or near certain trees or sacred spots, in witchcraft and in ghosts, as well as a more vague belief in a kind of supreme being. The various tribes have each their sacred animal or totem, which it is unlawful for them to eat or kill. Altogether this is an excellent report, and the accompanying maps make it of some value to anthropological students.

AN exploration of considerable importance has lately been undertaken by the East Siberian branch of the Russian Geographical Society (*Izvestia*, xvii. 1, 2; xviii. 3). M. Sibiryakoff, a well-known owner of gold-mines, having put a large sum of money at the disposal of this society, about twelve persons, thoroughly acquainted with the Yakutsk province from a many years' stay in different remote parts of it as political exiles, were invited to join in a detailed exploration—anthropological, ethnographical, linguistic, and economical—of the Yakut and Tungus population of the province. The exploration, which has now been carried on for three years, has resulted in the accumulation of most valuable materials. Anthropological measurements and photographs of Yakuts, Tunguses, and Russians were made by MM. Gekker, Mainoff, and Vitashevskiy, on a very large scale, and part of the data has already been published in the *Memoirs* of the East Siberian branch. Special excursions to inquire into the economical conditions of the population were made; all materials which are kept in the archives of the local administration, and which could be utilised for historical, ethnographical or economical purposes, were consulted. The common law of the natives was carefully studied, as also their folk-lore and their traditions; and, finally, the exploration was extended by the exiles who are kept in Sredne-kolymsk to the extremely interesting, and almost quite unknown, Yukaghires of the Arctic littoral; while S. Kovalik has nearly prepared for print a complete history and ethnographical description of the Yakuts of the Olekma region. At the same time E. Pekarsky, who speaks in Yakut as in his mother tongue, has prepared for publication a most elaborate and highly appreciated Yakut dictionary. For compiling it, he has utilised all formerly printed materials, as also many MSS. which were kept in the library of the East Siberian branch, and a considerable amount of notes collected by his comrades within the last fifteen years. A special sum was subscribed by M. Sibiryakoff for the publication of this dictionary.

A NEW process for preventing the decay of wood has recently been introduced, and extensive works set up at Millwall for treating timber. The inventor, Mr. Samuel Edward Haskin, has been engaged for the last twenty years in experimenting and perfecting the process in America. Hitherto the method adopted for preventing wood from decay has been by the withdrawal of the sap, and the injection of creosote or other antiseptic substances. The Haskin process, on the contrary, retains the sap, but destroys its germinative principle. To procure this result the wood to be treated is placed in a cylindrical heating-chamber, and submitted to a medium of superheated air at a pressure fourteen times as great as the normal pressure of the air. The substances composing the sap are by this means chemically changed, and form a powerful antiseptic mixture, which becomes consolidated with the fibre, thus strengthening and preserving the wood.

MR. H. L. RUSSELL is continuing his experimental investigations on the ripening of cheese, and, in conjunction with Mr. S. M. Babcock, has recently published an important paper describing what the authors consider to be a new factor in this process. Hitherto these changes have been solely ascribed to the direct or indirect action of the bacteria that are present in the milk, and the lactic acid bacteria have been credited with playing the chief *rôle* in this matter. But Russell and Babcock have shown that profound changes of a physical and chemical nature occur in milk in which bacterial fermentations have been excluded, and by means of carefully carried out experiments they have obtained results which they consider justify the assumption that these changes are of a non-vital character, and due to the presence of ready-formed enzymes in the milk as obtained from the cow. They have, moreover, succeeded in separating out proteid-converting (proteolytic) enzymes which, when applied to milk, exerted a curdling as well as a digestive function. The authors believe that the ripening of hard cheese, instead of being due solely to bacteria, is caused by the joint action of both organised (bacteria) and unorganised ferments (enzymes). This is a novel suggestion, and will doubtless stimulate research in this direction. Meanwhile the characteristic flavours of cheeses still remains a problem, and it is probable that in this department investigations may teach us to credit bacteria with yet more importance than we are even at present inclined to ascribe to them. The authors' memoir is to be found in the fourteenth annual report of the Wisconsin Agricultural Experiment Station, issued in December last. Agricultural research in this country may well take a lesson from the splendid work which flows so continually from the recently equipped scientific stations in the United States; formerly the investigator had but little more than German journals to take into consideration, but now he has to refer on all sides to American publications.

THE *Bulletin* No. 2 (December 1897) of the Laboratories of Natural History of the State University of Iowa consists of two articles—"The Coleoptera of the Lower Rio Grande Valley," by Mr. H. F. Wickham, and "The Ferns of Nicaragua," by Mr. B. Shimek. In the latter paper the number of species enumerated, including Ophioglossaceæ and Marattiaceæ, is 198, belonging to 39 genera, justifying the author's description of Tropical America as the "fern-paradise of the earth." (In the British Islands we have 38 species belonging to 17 genera.) The larger number of these were collected by the author in a botanical expedition undertaken for the University. The high mountains in close proximity to the sea afford a climate remarkably well adapted for the growth of ferns, which are stated to form the most conspicuous feature of the vegetation excepting palms. A large number are epiphytic, and they vary in size from tiny species of *Trichomanes*, with fronds only a fraction of an inch in height, to clinging "vines" like *Blechnum volubile*, single fronds of which often exceed 30 feet in length, or to splendid tree-ferns. The paper is illustrated by twenty excellent plates.

Farmers' Bulletin, No. 68, of the U.S. Department of Agriculture is devoted to a description of the black rot of the cabbage, and the best remedies or preventives, by Mr. E. F. Smith. The disease is due to *Pseudomonas campestris*, a parasite especially destructive to plants belonging to the Cruciferæ.

MESSRS. SWAN SONNENSCHEIN AND CO. have in the press a work on "Epidemic Diphtheria," by Dr. Arthur Newsholme. The work embodies a research on the origin and spread of the disease, from an international standpoint.

MESSRS. CROSBY LOCKWOOD AND SON ask us to state that the forthcoming work on "Submarine Telegraphs: their History, Construction, and Working," by Mr. Charles Bright, will be published very shortly, and to remind our readers that the subscription price ceases to apply on the date of publication.

A THIRD and revised edition of Mr. W. Arnold Buffum's interesting book on amber, entitled "The Tears of the Heliades, or Amber as a Gem," has been published by Messrs. Sampson Low, Marston and Co., Ltd. The volume brings together many facts of interest concerning the origin and decorative uses of amber.

THE determination of the density of a gas has, till comparatively recently, been regarded as an operation of great difficulty, requiring elaborate apparatus and a large quantity of material. In the course of his researches on argon and helium, however, Prof. Ramsay has shown that it is possible by direct weighing to arrive at a reasonably accurate result upon as small a quantity as thirty cubic centimetres. In two recent numbers of the *Comptes rendus* are two contributions to this subject by M. Th. Schlœsing, jun., in which he gives a most ingenious method of measuring the density of a gas, based upon the balancing of two columns of the gases in a U-tube. Two vertical tubes about one metre in length communicate at their lower ends by a three-way tap; in one is placed an easily absorbable gas of known density, such as carbon dioxide, and in the other the gas under examination. On allowing the columns to communicate through the tap, a state of equilibrium between the gas, carbon dioxide, and air is set up after about four minutes, and the level of the invisible surfaces of separation then determined by absorbing the carbon dioxide with potash. In order to reduce the unavoidable diffusion of the gases, very narrow tubes were taken (1·6 mm. to 2·7 mm. in diameter), with the resulting advantage of reducing the quantity necessary for a determination. In the second paper data are given for nitrogen, oxygen, and methane, from which it would appear that an accuracy of 1/1000 is obtainable upon five to seven cubic centimetres of gas. With hydrogen only was there a failure, the mutual diffusion of the two gases being too rapid to allow of equilibrium being set up. There can be no doubt that the method will admit of many useful applications.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. Robert O'Callaghan; a Horned Lizard (*Phrynosoma cornutum*) from California, presented by Mr. Charles Iseard; three Shaw's Gerbilles (*Gerbillus shawi*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

A PROBABLE NEW STAR.—In Circular No. 45 from the Wolsingham Observatory, dated February 14, the Rev. T. E. Espin states that an eighth-magnitude red star not in B.D. was found the previous night, its place being R.A. 7h. 12m. 16s., Decl. + 32° 19′ (1855).

NEW PHOTOGRAPHS OF NEBULÆ.—With a reflector having the extraordinary ratio of 1 metre aperture to 3 metres focal length, M. A. Rabourdin has taken some remarkable photographs of several nebulæ at the Meudon Observatory, and he gives a detailed account of them in *Comptes rendus* for January 31. On the ring nebula in Lyra he made three exposures—of twenty, thirty-five and fifty-five minutes. "These three plates," he remarks, "show that for this annular nebula the nebulosity of the interior increases with the time of exposure, whilst the total diameter increases very little. The final result is an elliptical nebula in place of the annular one taken with the short exposure. The photographs also show very plainly a star at the centre of the ring, which is, moreover, visible to the eye in the telescope; but neither the drawings of Herschel in 1833, Lord Rosse in 1844, nor that of Trouvelot in 1873, give any indication of it. Hence this would tend to show a comparatively recent change."

With an exposure of fifty minutes on the planetary nebula in Aquarius, a photograph was obtained showing two protuberances diametrically opposite, which would lead one to suppose that the central globe is surrounded by a diffuse belt analogous to Saturn's ring.

A photograph of the nebula in Andromeda, with only one hour exposure, is said to exhibit as much detail as those previously obtained with four times the exposure; and the nebula is so extensive, that it was quite impossible to photograph the whole region on one single plate.

A photograph of the nebula in Triangula shows that it is a beautiful spiral one.

The region of the Pleiades was also photographed, giving one hour exposure, with Alcyone in the centre of the plate. Even with this comparatively short exposure, MM. Henry have discovered nebulæ absolutely invisible in the telescope, enriching this region still more with two other new nebulæ surrounding Atlas and Pleione. This photograph also shows more than the beautiful chart of the Pleiades taken by MM. Henry, and exhibits additional streams of nebulous matter which apparently bind together certain stars of this group.

CARBON IN THE CHROMOSPHERE.—That carbon existed in the solar spectrum itself was at one time a matter of doubt, but its existence was established long ago by the early researches of Sir Norman Lockyer. Now, with the aid of the 40-inch telescope of the Yerkes Observatory, Prof. Hale has observed the presence of carbon in the chromosphere, and his paper on this subject is to be found in the December number of the *Astrophysical Journal*. The observations were made last September, and the green fluting near *b* was distinctly seen as a bright reversal in the chromosphere. M. Deslandres, who was visiting the observatory at the time, had no difficulty in seeing the lines, and they have since been observed by Profs. Runge and Keeler.

These results are interesting, in the light of the fact that the photographs of the total eclipse of 1896 show a decided influence of the prominences on the corona, and the examination of the corona itself at the last eclipse, for the presence of carbon might possibly have led to fruitful results.

PARALLAX OF SIRIUS.—In the *Monthly Notices* for January, Dr. Gill discusses a series of observations for the parallax of Sirius, made by him in 1888–89 with the Cape heliometer. The comparison stars used were both of 8·7 magnitude; one, which he denotes by γ, being 4310″ distant, and the other, δ, 4536″ away from Sirius, with respective position angles of 279°·17 and 101°·26.

From these observations he deduces a value of 0″·370 ± 0″·0097, which is in remarkably close agreement with his well-known result of 0″·370 ± 0″·009 from his 1881–83 observations.

Dr. Gill states that by this method of measurement it was possible to determine parallaxes so small as 1/50 of a second with some confidence—a degree of accuracy not previously attained in astronomical researches of any kind. He therefore thinks we may regard the parallax of Sirius as now satisfactorily determined, and that the corrections depending on a parallax of 0″·37 might with advantage be introduced in the apparent places of Sirius given in the national ephemerides.

WE note with pleasure that Mr. A. C. D. Crommelin, in the *Monthly Notices* for January, continues his paper which appeared in the December number, on the "Ephemeris for physical observations of Jupiter, 1898." We had been so long accustomed to seeing the late Dr. Marth's name attached to these and similar tables for the moon and other planets, that it was doubtful who would volunteer to fill his place; but we are glad to find that one so able as Mr. Crommelin has undertaken this task.

THE ATOMIC WEIGHTS OF NICKEL AND COBALT.

THE determination of the atomic weights of nickel and cobalt has attracted a considerable amount of attention during the last few years, the numbers obtained by different workers exhibiting relatively startling variations. Thus, including only the four most recent results, the values for cobalt vary between 58·78 (Hempel and Thiele, 1895) and 60·12 (Schützenberger, 1892). Similar variations observed for nickel by Krüss, led him to the conclusion that this metal contained a new element, to which he gave the name of "gnomium"; but recent work has not tended to confirm this view. In the *Proceedings* of the American Academy of Arts and Sciences for November and December last, are two important contributions to this subject, by Richards and Cushman and

Richards and Baxter respectively, giving the results of analyses of the bromides of nickel and cobalt; which show in a decisive manner that properly purified nickel and cobalt are homogeneous substances. After stating the advantages pertaining to the use of the bromides, for the sublimation and bottling of which a highly ingenious apparatus is described, they show how two totally distinct methods of purification, starting from metals of different origin, lead to a bromide of the same composition.

For nickel bromide the material was obtained from two sources—the "pure" nickel of commerce, and Mond nickel prepared by the carbon monoxide process. The steps for the purification of the first of these included fractional precipitation as sulphide, then as hydroxide, conversion of this through the bromide into the violet crystalline ammonia compound $NiBr_2 . 6NH_3$, and this, after several recrystallisations, converted through the oxide into spongy nickel. For the Mond nickel, in which a little iron was practically the only impurity, the same process was adopted, except that to remove alkalis the hydroxide was converted into sulphate and the latter subjected to electrolysis several times. After conversion into bromide, these were analysed, and for the final analyses further purification was attempted by repeated deposition by electrolysis. All three samples gave identical results, 58·69, for the atomic weight of nickel ($O = 16$).

The cobalt was purified with equal care, the cobalt bromide being obtained by two distinct methods of purification, the one through potassium-cobalt nitrite, and the other through a cobaltamine, and these again purified by a combination of both processes. The results of the three series were practically identical, the atomic weight of cobalt being 58·99 ($O = 16$).

While recognising that data obtained from one compound only are not sufficient to finally settle the atomic weights of these metals, the authors conclude that if "gnomium" exists, it must have an atomic weight about equal to that of nickel and cobalt; and hence, that the wide variations observed in the results of other experimenters cannot be considered a valid argument in favour of the late Prof. Krüss's doubtful discovery.

CRATER LAKE, OREGON.

THE Mazamas of the State of Oregon are no ancient tribe of redskins, but the members of a very active and most praiseworthy mountaineering club in the city of Portland. The President in his last annual address observed: "Within two years the name *Mazama* has been heard throughout the world, and to-day it stands as a synonym for all that is unique, progressive and inspiring in mountaineering societies"; and even if the European Alpine clubs hesitate to accept this statement in its entirety, all must agree that the second number of the publication entitled *Mazama* justifies the "guid conceit" the members of that lively club have of themselves. As no American University commands respect without a rousing "yell," so no mountaineering club can organise excursions without a "cheer," and this is the Mazamas':—

"Three cheers for the mountaineers,
'Rah! 'rah! 'rah!
Nesika klatawa sahele
Ma-za-ma."

The obscurest line is Chinook jargon for "We go up." Led with such a slogan, the Oregon Highlanders have carried many peaks by storm, and have opened to the public much of the grand mountain scenery of the Cascade Range. Part 2 of *Mazama* is devoted to the remarkable natural feature known as Crater Lake, to which the club made an excursion in 1896. The description is not a piece of amateur geography, but a solid description put together out of reports by the first scientific authorities.

Crater Lake is situated nearly in 43° N. and 122° W. It may be reached from several stations on the railway between Portland, Oregon, and San Francisco, by roads, usually bad, and as yet there is no house of any kind near its shore. Leaving the Southern Pacific Railway at Midford, one may reach it by 85 miles of road up the Rogue River valley. From Ashland a road of 95 miles must be traversed; but the best road—one which is practicable for bicycles—is from Ager, Cal., past the deserted Fort Klamath, a distance of 116 miles. The whole country is covered with dense coniferous forest. In approaching the lake, there is a steep climb for about three miles; then the forest-clad mountain slope gives place to a nearly level plateau, carpeted in autumn with flowers, across which one walks a few hundred yards with nothing to see, until suddenly a precipice of 900 feet yawns at one's very feet, and deep below the dazzling blue water of Crater Lake spreads far and wide. The weird grandeur of the scene accounts to the full for the superstitious awe with which the Indians of the district regard the lake.

Crater Lake may have been discovered in 1847, but the first authentic account of its existence came from a composite party of prospectors in 1853. A party of Californian gold-seekers crossed secretly into Oregon to search for a mythical lost digging of fabulous richness, and for as long a time as provisions lasted they were followed by a party of Oregonians who could not be shaken off. The rivals united at last, and, continuing the search for gold together, came upon Crater Lake, which they named "Deep Blue Lake," or "Lake Mystery." The next recorded visits were in 1862, 1865, and 1869. From that time its fame began to spread, but it was not geologically examined by experts until 1883. In 1885 a party of the United States Geological Survey, under Captain Dutton, was detailed to sound the lake and make a topographical survey of its surroundings; and a detailed contour map was constructed.

The roughly circular lake, from four to six miles in diameter, is without outlet, and without tributaries; the upper edge of the rim is a water-parting, from which streams radiate down the slopes towards the sea through deep cut valleys. The outer slopes have a gradient of from 10° to 15°, and are richly wooded. The inner slopes are precipitous, and allow of a descent being made to the water only at one or two points. The water-level stands 6239 feet above sea-level, and the crest of the rim varies from 520 to 1989 feet higher. The greatest depth ascertained in the lake is 2008 feet. A relief model of the lake and its surroundings has been constructed, and shows a remarkable similarity to the larger ring-craters of the moon. One island of some size rises in the lake in the form of a cinder-cone, bearing a well-marked crater on its summit. It goes by the name of Wizard Island, and a fantastically weathered islet is named the Phantom Ship.

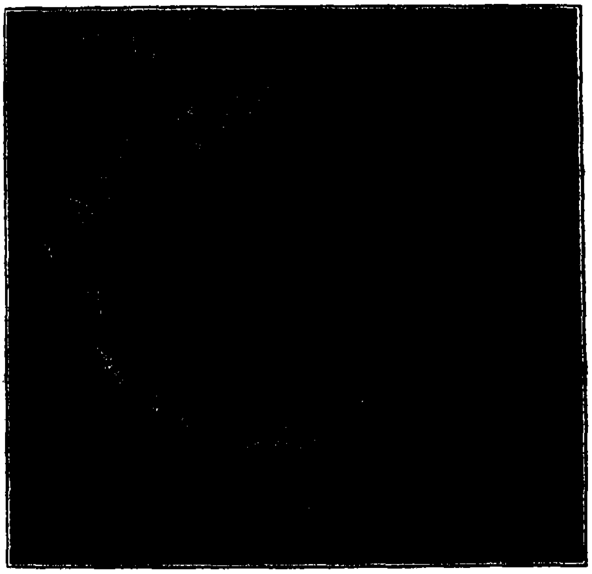


FIG. 1.—Photograph of a relief model of Crater Lake.

A description of the geology of the region is given by Mr. J. S. Diller. The rim is composed entirely of lava streams and beds of volcanic conglomerate dipping away from the lake. At one point, however, there is a remarkable lava-flow, which appears to have run down the inner slope.

The lavas of the rim are mainly andesites forming the earlier flows, but rhyolites associated with pumice occur among the later. There is no basalt on the rim, but basalts occur on the outer slopes several miles from the lake, being related to cinder cones adnate to the central crater. Numerous andesite dykes radiate from the lake, cutting through the older lavas as exposed on the inner slope. The inner slope appears to have been formed by fracture, and not by flow. The old crater did not occupy the whole extent of the present caldera; if it had done so the lava would have overflowed at the lowest part of the rim, but the whole rim is formed of lava-flows from some higher and now vanished centre. One very remarkable feature of the geology is the strong glaciation of the rim, shown by well-marked striæ and great morainic deposits. There are traces of glaciers radiating down the slope, in some cases to a distance of five miles. There is evidence of volcanic activity during the glacial period; on one of the peaks of the rim an ice-planed surface of old lava is covered by two layers of pumice separated by a flow of rhyolite. The severe floods, which must have accompanied eruptions at that period, would account for the vast masses of sediments which fill the radiating valleys. The observed phenomena can only be accounted for by the presence of a great volcanic peak covering the present area of the lake, and sweeping upward as a continuation of the present outer slopes. The probable history of this mountain is summarised thus:—

The history of Crater Lake and its rim began in the upbuilding, by normal volcanic processes, of a large volcano—to which the name Mount Mazama is given—comparable in the nature of its lavas and in its structure and size with the greater peaks of the Cascade Range. This volcano was active in the glacial period, lava and glaciers combining to mould its form. Somewhere near its final eruption, and perhaps in consequence of the rapid draining away of lava by the small cones near the base of the mountain, the molten material from the interior was withdrawn, the summit of Mount Mazama collapsed and sank away, leaving a huge gulf measuring six miles by four, and about 4000 feet deep. Volcanic activity continued on the floor of the caldera for some time; but since rainfall is in excess of evaporation in that region, water gradually accumulated to form the present Crater Lake.

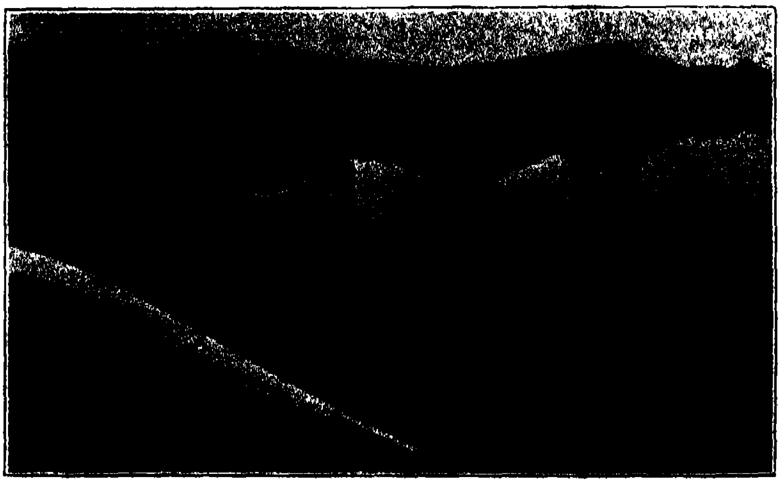

FIG. 2.—Crater Lake, showing Wizard Island.

The water of the lake is remarkably transparent, free from any visible organic matter, and fresh to the taste, but no analysis of its saline contents seems to have been made. The temperature of the water when examined in August 1896, averaged about 60° F. on the surface. The deep-temperature, taken by means of a Negretti and Zambra reversing thermometer in the unsatisfactory Magnaghi frame, was reported as 39° at 555 feet, 41° at 1040 feet, and 46° at 1623 feet. If these figures were trustworthy, it would appear that the water in Crater Lake still derives heat from the rocks; but if this interpretation is correct, it is difficult to account for the minimum at the maximum density point, unless indeed the water is saline enough to have a maximum density point perceptibly lower than that of fresh water. Dr. Evermann, of the U.S. Fish Commission, who made the observations, does not seem to have entire confidence in their accuracy.

Only three species of invertebrates were found living within the rim of Crater Lake—a frog, a snake, and a salamander. By the use of tow-nets several minute algæ were found in the water, and many minute crustacea, of which *Daphnis pulex pulicaria* was the commonest. Several larval insects, a leech, a species of *Gordius*, and one species of mollusc, an undetermined *Physa*, were also found. No fish could be discovered, but an attempt to introduce trout is to be made.

Dr. Merriam gives an elaborate classification of the life-zones on Mount Mazama, and a complete list of all the animals found; an extensive flora is also published, and in all respects the special number of *Mazama* is highly creditable to the Society which has produced it. The Mazamas are to popularise the lake for the use of tourists by introducing various attractions, which we fear will detract from its present charm by destroying the absolute wildness of the whole surroundings. H. R. M.

ADDRESS TO THE ROYAL ASTRONOMICAL SOCIETY.[1]

IT is the duty of your President at this annual meeting of our Society to address you on a very important subject. I allude, of course, to the award of the Gold Medal which is annually conferred by the Royal Astronomical Society on some astronomer who has rendered signal service to our science. The discharge of that duty is, perhaps, the most responsible official act which devolves on the occupant of this chair during his tenure of the distinguished position of President. I am to set forth the ground upon which on the present occasion the medal has been awarded by your Council to our distinguished Fellow, Mr. W. F. Denning.

The contributions of Mr. Denning to astronomy may be ranged under three heads.

(1) Discovery of Comets.

(2) Observation of Planetary Phenomena.

(3) Researches on Meteors.

It will be convenient for me to describe his work in these three different departments in the order just given. The first and second departments must, however, be treated with comparative brevity, for it is on the third department that your Council laid special stress in making their award.

(1) COMETS.

Each year usually brings the announcement of certain new comets, the discovery of such objects being the rewards of those observers who patiently scan the heavens, evening after evening and morning after morning, with the particular object of detecting these shy visitors to our skies. Mr. Denning has been one of those who have engaged in this work, and his success has been noteworthy. The following list gives the designations of five comets which have been discovered by our medallist.

Comet 1881 V.	Period, 8·68 years.
Comet 1890 VI.	
Comet 1891 I.	
Comet 1892 II.	
Comet 1894 I.	Period, 7·3 years.

While searching the skies for comets, Mr. Denning has not unfrequently discovered nebulæ which had escaped the attention of previous observers. No fewer than twenty new nebulæ have thus been added by Mr. Denning to the lists of those already known. Most of these new objects lie in the vicinity of the North Pole.

(2) PLANETARY OBSERVATIONS.

A striking characteristic of Mr. Denning's work is the methodical accuracy with which he has carried through whatever astronomical research he has in hand. Mr. Denning never spared himself any pains in the efforts necessary to give his work the inestimable charms of thoroughness and precision. This may well be illustrated by his planetary observations. We here specially refer to his work on Jupiter. It is well known that this very difficult object not only demands instruments of much optical perfection, but also calls for the exercise of the highest qualities which constitute a consummate astronomical observer. Mr. Denning, using a 10¼-inch reflector by Browning, made admirable sketches of the planet, in which he represented a remarkable amount of detail with a skilful pencil. But he was not content with work of this kind merely, however valuable such work may be. He watched the revolutions of a large number of spots individually, and determined as accurately as possible their times of transit over the central meridian of the planet. By such observations he ascertained the period of rotation of a large number of the most notable spots. Thus he illustrated the very interesting fact that the individual spots were animated by large proper motions on the surface of the planet. The famous red spot, so well known to every astronomer, has been in particular most diligently followed by Mr. Denning, and he has demonstrated the remarkable circumstance that its period of rotation varies from year to year. The results at which he has thus arrived are in close accordance with the observations of other accomplished astronomers.

---

[1] Delivered on February 11 by the President, Sir Robert Ball, on the occasion of the presentation of the Gold Medal to Mr. W. F. Denning.

(3) Researches on Meteors.

But the great work of Mr. Denning's scientific career, and that which has been mainly instrumental in deciding your Council to confer on him the distinction of the Gold Medal, has been connected with the very interesting subject of luminous meteors. The labours of Mr. Denning have been extensive enough to cover nearly every branch of the subject of meteoric astronomy. It would be difficult, indeed I may say it would be impossible, to render any adequate account of it within the limits of an address. I am, therefore, obliged to restrict myself to those more salient points which have specially been under the consideration of your Council.

The papers on luminous meteors communicated to the Royal Astronomical Society by Mr. Denning, and printed in the *Monthly Notices*, number altogether forty-two. In bulk they would, if collected together, constitute two-thirds of an ordinary annual volume in that form of the Society's publications. These papers are illustrated much more copiously than has usually been the custom with graphic and instructive figures.

A considerable number of these memoirs contain valuable lists of meteoric radiants derived either exclusively from Mr. Denning's own work at Bristol, or from his own observations in comparison with the work of other astronomers in the same field.

Mr. Denning's first published list of radiants appeared in 1876. It contains the determinations of twenty-seven radiant points, derived from his own observations of nearly 900 meteor tracks which he had himself mapped at Bristol between 1871–76. In this early list the periods of the recurrence of the showers are occasionally indicated by single days or short periods. But usually the month of recurrence is alone given. The list contains careful determinations of the radiant-points of the chief annual showers, such as Quarantids in 1873, the Lyrids in 1873 and 1874, the Perseids in 1871 and 1874, the Orionids in 1874, and the Andromedids in 1872. It is interesting to note that showers were found in correspondence with all but four radiants in the list contained in Mr. Greg's first general Star Shower Catalogue. This was published in comparison with Dr. Heis' similar list of the same year in the British Association volume of Reports for the year 1874. The four radiants which Mr. Denning was not able to corroborate are, it ought to be observed, marked as doubtful by Mr. Greg.

The latest list of radiants which has been issued by Mr. Denning, and the longest paper that he has as yet commmunicated to the *Monthly Notices*, was published in 1890. This important work gives remarkable evidence of the unflagging dilligence of our medallist. It contains a list of nine hundred and eighteen radiant points, deduced from the observations of no fewer than 9177 meteors, mapped at Bristol, between the years 1873 and 1889. This list, it should be remarked, includes repeated observations of the same radiants. This is the case not only with regard to the chief showers, but also with regard to various minor showers, whose yearly dates of recurrence cannot in the present state of our knowledge be assigned with any certainty.

Though many of these showers are but sparsely characterised by meteors, or, to use the more technical expression, are showers of great tenuity, they have not escaped the diligent scrutiny of our medallist. In such cases the dates are generally assigned to the single days when they have had apparently a maximum abundance. A column of supplementary dates have been added, which seldom range over more than a week. It will thus be seen that this catalogue presents an extensive series, not so much of averaged results as of exact and valuable individual determinations.

In other papers by Mr. Denning, mean results have been given which may be regarded as expressing, with regard to many important showers, the present state of our knowledge. For the chief meteoric showers a list of this kind was published in 1887. In it will be found mean positions for 1880, derived from fifteen years of observations of the radiant-points of the nine chief yearly showers. These contain the seven well-known periodic swarms of January, April, August, October, November (two showers) and December, adding to these the striking and very regularly visible displays of May 6 and July 28.

The most important contributions which our medallist has made to the general problems connected with luminous meteors are connected with the long duration of certain meteoric radiants. The fact of long persistency of radiant-points, and of close assemblages about the points of groups or compact families of simultaneous or successive meteor streams, is as old as Heis' first essays in meteor showers. It is, however, to Mr. Denning's persistent inquiries that we are mainly indebted for our knowledge of this subject. In his important paper of December 1884, Mr. Denning writes: "The fact of stationary radiants exhibiting visible activity during several months is a phenomenon so unaccountable and so utterly opposed to the approved theories as to the orbits of shooting stars, that it must receive a most crucial examination before it can be accepted."

The long-continued labours of Mr. Denning on this important subject have demonstrated the existence of these enduring radiants. The theoretical difficulties connected with the subject may be still not altogether removed, but we can hardly refuse assent to Mr. Denning's words when he says: "It must be conceived that a well-attested fact of observation, however hard to reconcile with known theories, ought on no account to be disregarded on account of its nonconformity."

It is, of course, known that the Perseids from the August shower are found, not only on the special nights with which the swarm is chiefly associated, but they are also displayed on many preceding and following nights. Mr. Denning has traced meteors of this group for the twenty-six nights from July 25 to August 19, and their radiant advanced in that interval over a distance of 40 degrees. In one of those admirable diagrams by which the interest of Mr. Denning's papers is so greatly increased, he gives a curve of the ordinary number of Perseids from one on July 25 to a maximum of 57 on August 10, and then declining to 1 on August 19. In his paper of 1890 Mr. Denning shows that the range of the Perseids is even wider still. I cite this case of the Perseids, because the gradual shift of the radiants as days and weeks passed by is, of course, no more than should be expected from the change of the place of the earth in its orbit. The extraordinary fact is that in the case of certain other showers, which are visible for weeks or months, the radiant undergoes no appreciable change in position. Mr. Denning selected for discussion in his "Memoir" of 1884 six special showers. Among these we may particularly note the α-β Perseids, which show a constant radiant from July 6 to November 30.

Such a paper as that to which I am now referring must be regarded as a classic which every one who is interested in the fascinating subject of meteors would do well to study. It is full of interesting facts and suggestions. We learn that in the catalogues published up to this date there are no fewer than 2100 radiants resulting from the projected paths of upwards of 6200 meteors; many of these are, however, duplicate observations of identical showers, and Mr. Denning adds that he does not believe the total number of well-defined streams would exceed 350.

In his introduction to the great catalogue of 1890, Mr. Denning has given a statement of his methods of work.

"My plan of work may be briefly described as follows. All the observations were made in the open air and from the garden adjoining the house. Attention was almost invariably given to the eastern sky. In mild weather I sat in a chair with the back inclined at a suitable angle, but on cold frosty nights I found it expedient to maintain a standing posture and sometimes to pace to and fro, always, however, keeping the eyes directed towards the firmament in quest of meteors."

Our medallist has recently published in the *Observatory* an instructive and opportune series of papers on the great showers of Leonids which may reasonably be expected in the next year or two. This subject is here discussed with characteristic wealth of knowledge and experience. He commences with the remark: "It may be safely said that in the month of November during the next few years, all astronomers and a large majority of the general public will become meteoric observers, for the phenomena presented will be of an exceptional kind and of a character to interest every one."

We all echo these words. I think I am justified in adding that much of the recently awakened interest in the subject has been due to the worthy example Mr. Denning has himself given us. Which of us would not be proud to emulate his single-hearted and enthusiastic devotion to the discovery of truth in this beautiful department of astronomy?

It is a matter of great regret to every one here assembled that our medallist, whom we greatly wish to honour, is not now present to accept in person our award. We regret this all the more when we learn that ill-health is the cause of his absence. We all join in a hearty wish for his speedy recovery, and in the hope that he may shortly be able to resume those observations which we receive with such interest and pleasure. We desire to assure him not only of our appreciation of his admirable work, but of the high esteem which we entertain for the spirit in which that work has been conducted.

On your behalf, therefore, I now hand the Gold Medal of the Royal Astronomical Society to our Secretary, to be by him transmitted to Mr. W. F. Denning in recognition of the valuable services to our science he has rendered, especially in the department of meteoric astronomy.

HISTORY AND OBJECTS OF THE PHYSICAL SOCIETY.[1]

I PROPOSE on this occasion to begin with a few words on the history and objects of our Society, and afterwards to glance briefly at the principal events of physical interest which have occurred during the past year.

The Physical Society was founded in 1874, and owed its origin mainly to the initiative of the late Prof. Guthrie. From the first years of its existence up to the present time it has included among its members nearly all the leading physicists of the United Kingdom.

In the early days our meetings were, by permission of the Lords of the Committee of Council on Education, held in the Physics lecture-room of the Royal College of Science at three o'clock on Saturday afternoons, members being allowed the free use of the laboratory apparatus for the illustration of their papers. The proceedings were at that time rather less formal than is customary at present. The papers were rarely, if ever, "referred" before being read; often, indeed, they were read long before they were actually written, while a large proportion of the communications were of a purely oral character, and never intended for publication at all, except perhaps in the short notes which the reporter sent to the scientific journals. Special prominence was given to experimental demonstrations illustrative not only of original researches, but also of such work carried on outside the Society as happened to be attracting attention at the time. . . .

Under the somewhat lax *régime* which then prevailed, it necessarily happened that the communications made to the Society were not always of a very high order of merit. . . . But from the very beginning the Council has always been careful not to print in the *Proceedings* anything that was not of sound scientific value, and while the number of important papers that have been published through the medium of the Physical Society is large, very little of doubtful quality has found a place in the *Journal*.

The first material change in our routine took place in the year 1889, when the day and hour of meeting were altered from Saturday afternoon at three to Friday at five o'clock. . . . I may here mention that the Council has more than once considered whether it might not be expedient to hold our meetings in the evening. Many, no doubt, would consider this preferable, but the balance of convenience appears to be clearly in favour of the afternoon. . . .

During the South Kensington epoch the Physical Society published and presented to its members a number of valuable books, including, among others, Prof. Everett's well-known treatise on the C.G.S. system of units and the works of Wheatstone and of Joule. It also issued twelve volumes of *Proceedings*, in which were collected such of the communications to the Society as had been approved for publication. By an arrangement with the proprietors of the *Philosophical Magazine* the same papers were also (as now) printed in that journal, being thus, to the author's great advantage, assured of a wide circulation throughout the scientific world. In the same period, notwithstanding the small amount of the annual subscription paid by members and of the composition fee for life membership, the Society's income so far exceeded its expenditure that it was able to accumulate and invest a capital of nearly 3000*l*.

When the Society entered upon its twenty-first year with a position which, if somewhat unpretending, was well recognised and firmly established, it was felt that the time had come when, in the interests of physical science, something more than had been already achieved might fairly be demanded of it. British physicists had long been at a serious disadvantage in that they were without any means of readily ascertaining what was being done by their fellow-workers in other countries; with the multiplication of scientific literature the need of some periodical digest similar in character to the German *Beiblätter* was becoming year by year more urgent. To endeavour to meet this want was a duty which clearly devolved upon the Physical Society, and the Council anxiously considered the question whether the publication of monthly abstracts of physical papers appearing in foreign journals could be undertaken by ourselves.

The only serious objection to the enterprise was of a financial nature. The work, if it were to be carried out efficiently, would certainly necessitate an annual expenditure exceeding by some hundreds of pounds the total income of the Society. This could only be met by raising the amount of the annual subscription and composition fee, which, as I have mentioned, were unusually low. But it is a delicate and difficult matter to ask existing members of a society for increased subscriptions unless very excellent reasons can be shown for the demand. The Council therefore determined that they would publish a series of abstracts for one year at least before taking any steps to provide additional income, defraying the cost from cash in hand and, if need should arise, drawing upon the invested capital. In this way it was hoped to convince members of the utility of the undertaking which they were to be called upon to support.

I need not remind you of the highly satisfactory result of the experiment. The work of the able and assiduous body of abstractors whose names appear on the cover of our *Proceedings* was on all sides cordially approved, and at a special general meeting, held in 1896, a resolution submitted to the Society for increasing the subscription to two guineas per annum was passed almost, if not quite, unanimously. The number of those who in consequence of this increase have resigned their membership has been unexpectedly small, while on the other hand many of the life members have, in response to the invitation issued to them, voluntarily contributed an additional fifteen guineas to the funds of the Society, in recognition of the fact that they are now in enjoyment of greater and more costly advantages than were contemplated at the time when they paid their very moderate composition fees. To such as have not yet responded I venture to repeat the invitation.

Although the abstracts were actually published for two years before the increased subscriptions began to come in, the whole cost was met out of uninvested cash, supplemented by grants liberally made by the British Association and the Royal Society, and it was never found necessary to draw anything at all from the reserve fund. I wish to emphasise this fact because the abundant caution properly exercised by the Council in entering upon a new and uncertain enterprise appears to have led to a very general impression that the Society had outrun its means and was on the verge of bankruptcy, whereas in truth it was never in a more prosperous financial condition than it is at present.

On October 26, 1894, the Society met for the first time in this room. Although the privileges so generously accorded to us by the authorities at South Kensington were highly valued, it was nevertheless deemed advisable that we should leave the home of our youth and seek a footing in Burlington House, the headquarters of scientific associations. Here the Chemical Society offered us a most kindly and cordial welcome, and provided us with a meeting-place which is not only more generally accessible than the old one, but is also on other grounds more convenient to most of our Fellows.

---

[1] Presidential Address to the Physical Society. (Abstract.) February 11. By Shelford Bidwell, F.R.S.

By this time the general affairs of the Society had assumed a more business-like condition. Amongst other things, greater care was exercised with regard to the acceptance of communications. I need hardly say that no paper is in these days allowed to be read unless it has been first referred to some competent authority and favourably reported on. The most distinguished physicists in the kingdom have given their services as referees, and our heartiest thanks are due to them for the care and patience which they have ungrudgingly bestowed upon a somewhat ungrateful task.

The practice was also introduced of putting the more important papers into type before they were read, and distributing proofs among such of the Fellows as were known to be specially interested in the subjects to which they related. This course has led to a considerable improvement in the value of the discussions.

The most recent step in advance consists in the adoption of a scheme for greatly extending the list of journals from which the monthly abstracts are made. Hitherto the papers abstracted have been exclusively such as had been published in foreign journals, and were of primarily scientific interest. In the present year, as the result of an agreement with the Institution of Electrical Engineers, the number of the abstracts is to be largely increased, British publications and papers of a technical character being included in their scope. The arrangement in question is open to the objection that it entails the loss of our monopoly in the publication, for members of the Institution of Electrical Engineers will, like ourselves, receive copies of the abstracts, and will share with us whatever credit attaches to their production. The objection, however, appears to be in the main only a sentimental one, and of small weight in relation to the substantial advantage accruing to our members—an advantage which could not possibly have been provided out of our own unaided resources. [Reference was then made to the advantages afforded by the Physical and other kindred Societies in promoting friendly intercourse among fellow-workers in a particular branch of science.]

Through the kindness of certain influential gentlemen belonging to the Society, we have from time to time been afforded the opportunity of holding a meeting in some well-known physical laboratory either in town or in the country. I myself have had the privilege of taking part in most agreeable pilgrimages to Oxford, Cambridge and Bristol, and have also been among those who enjoyed the hospitality of Profs. Adams, Carey Foster, Ayrton and Thompson at their laboratories in London. I have pleasure in announcing that the Council has accepted an invitation from our Fellow, Mr. Porter, to go to Eton for the next meeting on February 26, and I trust that our appreciation of his kindness will be testified by a large gathering. It is a little difficult to beg for favours, but I may be allowed to suggest to those who are in a position to exercise similar hospitality, that they have it in their power to contribute, in a material degree, and in more than a merely scientific sense, to the well-being of the Society.

[The second part of the address dealt with the discovery of the Zeeman effect; some of the principal papers published by the Physical Society in 1897; the appointment of the National Physical Laboratory Committee, and the foundation of the Röntgen Society.]

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE annual general meeting of the Institution of Mechanical Engineers was held in the theatre of the Institution of Civil Engineers on the evenings of the 10th and 11th insts. The usual formal proceedings having been gone through, the retiring President—Mr. E. Windsor Richards—introduced the new President, Mr. Samuel W. Johnson, who is locomotive superintendent to the Midland Railway. There were two papers down for discussion, and there was also an adjourned discussion on a paper entitled "Mechanical Features of Electric Traction," which had been read and partially discussed at the last meeting of the Institution. This paper was contributed by Mr. Philip Dawson, who is largely interested in the introduction of mechanical appliances in connection with electrical engineering into this country from America. Under these circumstances it was natural that the contribution should be of a general rather than a scientific character. The prominent feature in the paper was the fact that electrical traction has spread so rapidly in America, whilst very little has been done in this country. For instance, out of a total of nearly 15,000 miles of tramways in America in the year 1895, 12,583 miles are worked electrically. Cable traction, which was at one time so popular, and which seemed to have so promising a future before it, has been quite eclipsed by electrical methods, there being only 600 miles of rope tramway in the States in the same year. Steam has even a lower total, there being but 519 miles. Horse traction supplies the balance of something over 1200 miles. Great Britain and the Colonies in the year 1896 had but 167 miles of electric tramway, thus being far below Germany, which had a total of 618 miles. The only other European country having more than 100 miles was Austro-Hungary, with a total of 120 miles. Belgium had 90 miles, France 67, Italy 50, and Switzerland and Russia 30 miles each; whilst other European countries contribute 30 miles altogether.

It is not necessary we should follow the author in the practical details he gives regarding the various features of motors, trucks, cars, permanent way, conductors, methods of transmission, generating stations, &c. The long discussion on this paper resolved itself very largely into a controversy as to whether English engineers should follow American precedents. Prof. Unwin, in the speech that he made, entered a timely protest against the spirit of detraction which animated a good many of the speakers. As he said, American engineers may not be perfect in all their practice, and it is quite possible improvements may be made upon their methods, still they have had considerable experience, and what they have done represents actual work, whilst in this country we have practically no precedents in regard to electrical tramway practice.

The only paper read at the meeting was a contribution by Prof. Frederic W. Burstall; it embodied the first report of the Gas Engine Research Committee that had been appointed by the Institution, and of which Prof. Alexander Kennedy is the chairman. The object of the experiments described was to determine the effect produced on the economy of gas engines by altering one or more of the conditions which govern their working. The problem is one of a complex nature and presents considerable difficulties, especially as the gas engine has not like the steam engine been made the object of investigation by many authorities for a great number of years. The factors considered by the Committee were the amount of compression, the speed, the ratio of air to gas, and the amount of heat rejected through the walls of the cylinder. The engine used was of small size, perhaps too small to afford altogether satisfactory results; but the Committee were not to blame for this, for they had to work with such tools as they could command. The nominal power of the engine was 2 N.H.P., and the maximum that could be developed was 5 I.H.P; it was made by Messrs. Fielding and Platt, of Gloucester. The author stated that an increase of compression in a gas engine is often regarded as being conducive to more economical results, but it is uncertain whether the increase in economy is really due to the compression alone. It is, perhaps, fair to state that the Committee recognised that the absolute economy of the engine tried—which was specially constructed for experimental purposes—would be inferior to the economy that could be obtained by a larger motor; still, it was concluded that the comparative economies under different conditions would not be different in the two sizes; moreover, it was stated that it would have been impossible to measure with precision certain quantities, such as the volume of air, had the engine been larger. The compression employed in the experiments varied between 35 lbs. and 90 lbs. per square inch. The observations taken included measurements of the gas and of the air supplies, measurement of heat rejected into the jacket, sampling of exhaust gases, and determination of the I.H.P. developed. Seventeen tests were taken, and the mechanical efficiency of the engine was found to vary from 76 to 84 per cent., the mean value of the whole seventeen tests being 81 per cent. On a full power test the engine was running at 197 revolutions per minute, the compression per square inch absolute was 103 lbs., the ratio of clearance to cylinder volume was 0·25, and the ratio of explosions to the maximum possible was 92 per cent. Under these circumstances the

I.H.P. was 5·10, the gas per I.H.P. per hour 20·35 cubic feet, the heat expended per I.H.P. per hour was 12,186 thermal units, or 10·95 thermal units per explosion. The thermal efficiency was 21 per cent. Taking one of the low-speed experiments, with the ratio of air to gas of 10·4, the compression per square inch absolute was 86 lbs., the ratio of clearance to cylinder volume was 0·37, the revolutions per minute were 117·6, and the ratio of actual explosions to the maximum possible was 75 per cent. With these conditions the I.H.P. was 1·84, the gas used per I.H.P. per hour 28·2 cubic feet, the heat expended was 17,041 thermal units per I.H.P. per hour; that gave a thermal efficiency of 15 per cent., a result which, as the author remarks, was distinctly uneconomical. In the following test the compression was 102 lbs. absolute, the ratio of clearance to cylinder volume being 0·25, the revolutions and the I.H.P. were practically the same, but 31 cubic feet of gas were used per I.H.P. per hour; the thermal efficiency, therefore, being 13·6 per cent, although the compression was so much higher than in the previous test mentioned, almost approaching that of the full-speed test first referred to.

In connection with this matter, the fact commented upon during the discussion may be referred to. The older gas engines were designed for lower pressures; and it is found with them that increasing the compression does not add to economy. The ratio of clearance has an important bearing on the case, the port surface acting as a condenser, and an increase in the compression induces a degree of cooling which is not economical. There is also the loss by leakage through the indicator, the proportion of which will be considerable in the case of a small engine. The Wayne indicator used during the experiments has a rotating piston not touching the sides of the cylinder, and therefore admitting of constant leakage. In the steam engine the loss from leakage through the indicator is comparatively unimportant, being governed by the pressure present in the cylinder at any given time. With the gas engine, however, this is different, as the working mixture escapes through the cylinder before ignition. One of the speakers humorously likened the effect of an indicator on a small gas engine to a big whistle on a steam launch boiler. He said that in the early days of steam launches a friend of his had a small paddle yacht with a very big whistle, which was fitted in order that he might let his friends know when he was coming. He found, however, that when he paddled he could not whistle, and when he whistled he could not paddle.

A brake was used in the experiments, and perhaps it would have been better if Brake H.P. had been given in the tables. It was found that the measurement of gas by means of an ordinary meter, although giving a correct aggregate result, possessed the disadvantage of not controlling the fluctuations of pressure in the mains; a calibrated gas-holder was therefore used. The amount of air used per stroke was measured by a meter into which air was forced by a Sturtevant blower, the pressure being kept constant by means of a gas governor; precautions were taken to prevent back ignition; a rubber gas bag was used to obviate the fluctuation in pressure in the meter during the suction stroke. No difficulty was found in working this apparatus. Records were taken of pressure and temperature of the air; measurement of the heat rejected was effected by running the cooling water from the calibrated tank through the water jacket and thence to the discharge, the capacity of the tank being sufficient to hold water for a single test. The temperatures of the inlet and outlet water were taken. The glass stems of the thermometers were attached to brass plugs by means of soldering with Thomas's fusible metal, which enables glass and brass to be fixed together with a pressure-tight joint. To obtain samples of the exhaust gases, a single bubble of gas was taken from just below the exhaust-valve after each explosion stroke by means of suitable apparatus, which was illustrated by a wall diagram shown during the reading of the paper. The Wayne indicator used to find the I.H.P. was considered superior to the Richards, Crosby, Darke or Tabor indicators. It was made by Messrs. Elliot Brothers. This indicator appears to be similar in principle to one introduced by Mr. Michael Longridge some years ago. For reducing pencil friction to a minimum, cards of smoked mica were introduced in place of the usual paper. An iron tube was used for ignition, electrical methods having been tried, but were not found satisfactory.

The author, in giving a summary of the experiments, concluded that it was probable that the influence of increased compression on economy was due to the fact that weaker charges can be burnt completely during the stroke when the compression is high. It should be stated that in the test of which we have given particulars, in which the thermal efficiency was 21 per cent., the author considered that more economical results than this could be obtained, as the ratio of air to gas was 8·6, which was certainly higher than necessary. It may be added that the best mixture for a modern gas engine is considered to be one of gas to ten of air by volume. The report continued that the test seemed to indicate that economy depends on the choice of the correct ratio of air to gas, and that this ratio increases with compression. The number of experiments was not yet sufficient to determine what any ratio was for any given compression, but it is stated that further tests are to be made for arriving at this important point.

The summer meeting of the Institution will be held this year in Derby.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. Charles Godfrey, of Trinity College, has been elected to the Isaac Newton Studentship in Physical Astronomy.

The General Board of Studies propose that the Professorship of Surgery, held by the late Sir George Humphry, be suspended until the Senate shall otherwise determine. Meanwhile the duties of the office are to be discharged by a Reader in Surgery, at a stipend of 240*l.* a year.

The General Board also propose to recognise the continued liberality of the Royal Geographical Society in providing for the endowment of geographical teaching, and the importance of encouraging the study of the subject in the University by raising the present Lectureship, held by Mr. Yule Oldham, to a Readership in Geography, with a total stipend of 200*l.* a year.

DR. KARL HÜRTHLE, assistant professor of physiology at Breslau, has been appointed professor of physiology and director of the Physiological Institute, in succession to the late Prof. Heidenhain.

THE Council of King's College, London, have received from the Trustees of the British Museum a valuable series of fossils, in aid of the teaching collection for the Geological Laboratory in the Science and Engineering Faculty.

AN anonymous donor has offered 10,000*l.* for the completion of the extension scheme of Aberdeen University, on the condition that 20,000*l.* is obtained from the Government for the same object. The Chancellor of the Exchequer has agreed to receive a deputation on behalf of the movement for the extension of the University.

Science states that at the semi-annual meeting of the Board of Trustees of Beloit College it was announced that the College had received a gift of 25,000 dollars for the endowment of the chair of Chemistry, now occupied by Prof. E. G. Smith. The donor wishes to remain anonymous. It was also reported that the sum of 70,000 dollars had been raised towards the 100,000 dollars necessary to secure Dr. Pearson's gift of 50,000 dollars.

THE rapid progress of medical education and the enlargement of the requirements of the Examining Boards have rendered it imperative to provide more space for the teaching of several important subjects in the London Hospital Medical College. Consequently a large portion of the College is about to be rebuilt and enlarged, and all the necessary class-rooms and laboratories provided. It is intended that the work will be completed by the commencement of next winter session.

THE magnitude of the operations of the Department of Science and Art may be judged from the figures given in the Calendar of the Department for 1898. The total number of individual students in science classes held under the auspices of the Department was 157,984. The subjects which attracted more than ten thousand students in the year covered by the Calendar are: Mathematics (Stages 1, 2, 3), 40,244; Inorganic Chemistry (Theoretical), 26,433; Practical Plane and Solid Geometry, 24,069; Physiography, 22,409; Machine Construction and Drawing, 19,952; Building Construction, 15,195; Magnetism and Electricity, 12,591; Hygiene, 10,143. At the other end of the scale we find that mineralogy only attracted 152 students, and zoology 189. Nine of the departmental subjects are practical; and the number of students who took practical work is as follows: Inorganic Chemistry, 15,169; Magnetism and Electricity, 2694; Sound, Light, and Heat, 1793; Organic Chemistry, 1538. The remaining practical subjects—human physiology, general biology, zoology, botany, and metallurgy—divided 1852 students between them. There are now 169 Schools of Science in which organised courses of study are taken in connection with the Department, and the number of students attending them is 20,879.

SCIENTIFIC SERIALS.

THE most important contribution to *Himmel und Erde* for this month is a long paper on the terminal moraines of North Germany. The other papers comprise one in which is given the conclusion of a lecture by Dr. Drygalski on Greenland, dealing mainly, in this part, with the habits and customs of the Esquimaux; and another by Herr G. von Gleicke treating of the existence of an intra-mercurial planet or planets, generally surveying the various theories that have been put forward to explain the motion of the perihelion of Mercury. The only result that appears certain in the paper is the practical confirmation of the reality of the motion, originally determined by Le Verrier. The presence of a single planet or of a ring of meteoric matter; the existence of an unknown satellite of the planet itself, or an ellipticity in the figure of the sun; an alteration in the expression of the law of gravitation or the introduction of terms suggested by electrodynamic considerations; all seem to offer insuperable objections, or to be based on pure empiricism. The enigma is not solved yet. The subjects to which the shorter notes refer have generally been mentioned in these columns. They include some account of the Greenland Meteor; the sinking of the surface of the earth in the neighbourhood of the Canadian lakes, and its effect on the Niagara Falls; the depth of the sea and the determination of ocean currents around Australia derived from floating bottles. A short notice is also added of a proposed attempt on the part of MM. Godard and Surcouf to reach the North Pole by means of ballooning. The expedition would start in the summer of 1898, selecting Spitsbergen as a base of operations. The peculiar feature of the attempt seems to consist in carrying twelve small balloons, filled with hydrogen to serve as a gasometer to supply the main balloon, which is of gigantic dimensions, with the gas which may leak or waste. M. Godard counts on spending sixty days aloft, and to carry with him the means of support of no less than seven people, among whom will be found a chemist, a meteorologist, and a physician.

Memoirs of the Caucasian Branch of the Russian Geographical Society, vol. xviii.—On the distribution of precipitation in Caucasia during the spring and summer of 1894, by A. Woznesensky, with four maps.—Journey in the Chernomorsk district, in 1894, by N. Alboff; with a map (on the scale of seven miles to an inch) of the Chernomorsk district and the western part of the district of Sukhum; and botanico-geographical researches in Western Transcaucasia, by the same author, being a continuation of his paper inserted in a preceding volume of his *Memoirs*. In this paper two important excursions across the main ridge of Abhasia are described. The flora of the limestone-mountains having been the special subject of studies, it is dealt with in detail. The rare new species *Amphoricarpus elegans*, which was formerly found at two places only of Abhasia and Mingrelia, was met with in thousands. A bush-like *Campanula*, which M. Alboff considers as a new species, was found and was named *C. regina* for its rare beauty. Numbers of other rare species were found. Detailed lists of the limestones' fauna in Abhasia and Mingrelia are given. In addition to the glaciers previously discovered on the northern slope, a hanging glacier was found on the southern slope. Very interesting remains of the ancient population of the region are mentioned.—On the Kumyks, anthropological sketch by J. Pantukhoff. The paper contains a sketch dealing with the possible origin of this Tartar stem, anthropological measurements made by the author, and a comparison of the same with measurements on other Caucasian stems.—The Pshaves and their land, by D. Khizanachwili.—A journey in the central portion of the Mountain-Chechnya, by Madame A. Rossikoff, with a map three and a half miles to the inch. Detailed and lively account of a journey in that imperfectly known part of Daghestan, the seat of Shamil's wars.—Statistical description of, and statistical data relative to, the provinces of Baku, Kars, Erivan, Daghestan, and Elisabethpol.—On the condition of glaciers and of the lakes on the northern slope of Central Caucasus, by K. Rossikoff.—In a very interesting appendix we find (1) a beautiful atlas of eight ethnographical maps of Transcaucasia, one for each separate province, on the scale of thirteen miles to an inch (it is the work of E. Kondratenko); (2) a map of the distribution of the Armenian population in Asia Minor, on the basis of V. Cuinet's data, 1890–94, accompanied by a paper by General Zelenyi and Colonel Sysoeff; and (3) the distribution of Armenian populations in Transcaucasia.

WE have received the number of the *Irish Naturalist* for February, and are always glad to say a word on behalf of these local natural history journals, which have done so much to encourage the early enthusiasm of many who have afterwards become eminent naturalists. In the present number Mr. Allan P. Swan describes and figures a new species of *Leptolegnia, L. bandoniensis*, belonging to the *Saprolegniaceæ*.

THE *Journal of Botany*, in its numbers for January and February, still continues to cater chiefly for descriptive and "critical" botanists. Mr. F. Townsend describes and figures a new species of *Euphrasia, E. canadensis*, from the neighbourhood of Quebec; and Miss Ella M. Tindall enriches British Hepaticæ with a species new to science, *Fossombronia Mittenii*, from North Devon, which is also figured

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 20.—"Fergusonite, an Endothermic Mineral." By William Ramsay, Ph.D., LL.D., Sc.D., F.R.S., and Morris W. Travers, B.Sc.

The mineral fergusonite, discovered by Hartwall, occurs in felspar and mica deposits, in the same manner as most of the rare Norwegian minerals, such as euxenite, orthite, samarskite, &c. The position in which such minerals are found, embedded in masses of felspar, or encrusted with mica, leaves the question of their origin an open one. Whether they are deposited in the felspar by water, or whether they are contemporaneous with the felspar, is a matter of speculation. Fergusonite is a black lustrous mineral, not unlike obsidian in outward appearance, but of considerably higher density. Seen under the microscope, even with the highest power, there is absolutely no sign of crystalline structure, though in thin slices the substance is translucent, and transmits yellow-brown light. It is, however, macrocrystalline, occurring in quadratic sphenoids. It is quite homogeneous, and displays no sign of cavities. Like similar minerals, it contains helium, which is expelled on the application of heat.

But this mineral presents a peculiarity, which has led us to publish this note. When heated to a temperature not exceeding 500° or 600°, it suddenly becomes incandescent, and evolves much of its helium; while its density decreases.

The analysis of the mineral was kindly undertaken by Miss Emily Aston, to whom we desire to express our indebtedness.

It showed that fergusonite is mainly a niobate of yttrium, containing oxides of uranium, but in no great quantity.

The gases evolved by the incandescence of nearly 5 grams (4·852) of the mineral, heated in a vacuous tube, were analysed and found to consist of helium, hydrogen, carbon dioxide, and nitrogen.

The density was determined before and after heating. Great care was taken to make sure of the absence of air-bells, by warming the powdered mineral under water in a vacuum, before weighing it.

Density before heating	5·619
,, after ,, ...	5·375

It is thus seen that the mineral loses density on incandescence.

The amount of heat lost by this curious mineral in parting with its helium was determined. The plan of operation was to burn in oxygen a known weight of hydrogen, ascertained by measuring it, under a small platinum crucible, in a calorimeter. The rise of temperature was noted. This operation was repeated several times, so as to standardise the calorimeter. Some grams of mineral were then placed in the crucible, and the operation was repeated; the heat evolved by the incandescing mineral added itself to that from the burning hydrogen, and the rise of temperature was greater. Knowing the heat of combustion of hydrogen, a simple calculation gave the heat evolved by the exothermic change in the mineral.

Various questions are raised by the behaviour of this interesting mineral. Its evolution of heat, accompanying its parting with helium, suggest the idea that it is a true endothermic compound of helium. Had its density, as is the case with alumina, and with other oxides which rise spontaneously in temperature when heated, increased instead of decreased, the evolution of heat might justly have been ascribed to polymerisation. But an evolution of heat, accompanied by a *fall* in density, leads to the conjecture that the loss of energy is the result of the loss of helium; and that, conversely, the formation of the compound must have been concurrent with a gain of energy. That the helium is actually in combination, and not retained in pores in the mineral, is evinced by there being no pores in which the helium might be imprisoned. Surface-absorption is equally out of the question, for the mineral is compact. The only remaining possibility is that the helium is in chemical combination. And if this is true, then the compound must be an endothermic one.

There is one other substance at least which decreases in density, while it evolves heat; that substance is water, in changing into ice. The effect of compressing ice is to lower its melting point, and at the same time to reduce its heat of fusion. At a sufficiently high pressure there would be a continuous transition from ice to water, no heat change taking place during the transition. Matters would be in a similar condition to those which accompany the change of a liquid into gas at the critical temperature; the smallest alteration of temperature would be enough to bring about the change. In speculating on the origin of such a remarkable compound, is it not allowable to guess that it represents a condition of our earth realised only before solidification had set in? That these minerals, containing the rare elements, represent a portion of the interior of our planet; and that under the enormous pressure obtaining at the centre, combination with helium was an exothermic event; and that such compounds, having by some unexplained accident come to the surface of the globe, where they are no longer exposed to such pressure, they have, in consequence of the change, become endothermic? The frequency of the helium spectrum in the stars, and its presence in the sun, makes it less improbable that some such explanation may lie not far from the truth.

February 3.—"Note on the Experimental Junction of the Vagus Nerve with the Cells of the Superior Cervical Ganglion." By Dr. J. N. Langley, F.R.S., Fellow of Trinity College, Cambridge.

The author concludes from his experiments that there is no essential difference between the efferent "visceral" or "involuntary" nerve fibres, whether they leave the central nervous system by way of the cranial nerves, by way of the sacral nerves, or by way of the spinal nerves to the sympathetic system. All of these fibres he takes to be pre-ganglionic fibres. And he thinks that any pre-ganglionic fibre is capable, in proper conditions, of becoming connected with any nerve cell with which a pre-ganglionic fibre is normally connected; although apparently this connection does not take place with equal readiness in all cases On the whole it appears that the functions exercised, both by pre-ganglionic and by post-ganglionic fibres, depend less upon physiological differences than upon the connections which they have an opportunity of making during the development of the nervous system and of the other tissues of the body.

Physical Society, Annual General Meeting, February 11, 1898.—Mr. Shelford Bidwell, President, in the chair. The Report of the Council was read by Mr. Elder. Dr. Atkinson then presented the Treasurer's Report, and informed the Society of the improved condition of its finances. The difficulties of the previous year had arisen from the expenses incurred by the publication of abstracts of current scientific literature; those difficulties had been surmounted without drawing upon the reserve fund. Very few Fellows had objected to the increase of subscription. In acknowledgment and appreciation of the abstracts, now presented to all Fellows, many of the original life-members had lately made additional voluntary donations to the funds of the Society, thus sharing with new Fellows the extra outlay involved by the abstracts. It was to be hoped that all life-members would adopt this course, more especially as the scope of scientific literature covered by the abstracts was now being extended to British as well as to foreign sources. Votes of thanks were passed to the Council, the officers, and to the Council of the Chemical Society for the use of their rooms at Burlington House. Two Honorary Fellows were unanimously elected by ballot, *i.e.* Riccardo Felici, professor in the University of Pisa; and Emilio Villari, professor in the University of Naples. Council and officers for the forthcoming year were elected as follows. President: Mr. Shelford Bidwell. Vice-Presidents (who have filled the office of President): Dr. J. H. Gladstone, Prof. G. C. Foster, Prof. W. G. Adams, The Lord Kelvin, Prof. R. B. Clifton, Prof. A. W. Reinold, Prof. W. E. Ayrton, Prof. G. F. Fitzgerald, Prof. A. W. Rücker, Captain W. de W. Abney. Vice-Presidents: Prof. C. Vernon Boys, Major-General E. R. Festing, Mr. G. Griffith, Prof. J. Perry. Secretary: Mr. H. M. Elder, 50 City Road, E.C. Foreign Secretary: Prof. S. P. Thompson. Treasurer: Dr. E. Atkinson. Librarian: Mr. W. Watson. Other Members of Council: Prof. H. E. Armstrong, Mr. Walter Baily, Mr. L. Clark, Dr. A. H. Fison, Mr. R. T. Glazebrook, Prof. A. Gray, Prof. J. Viriamu Jones, Mr. S. Lupton, Prof. G. M. Minchin, Mr. J. Walker.—The President then read an address in which the aims and history of the Physical Society were outlined. (An abstract of this address is published in the present issue, p. 378.) Prof. Rücker said that among the new and useful departures lately made by the Physical Society the institution of a presidential address was particularly worthy of notice; it was very desirable, from time to time, to hear a summary of what had been achieved during the year; it was also desirable that the objects of the Society should be, from time to time, definitely stated; this departure had been fully justified by the address of Mr. Shelford Bidwell.—A paper by Mr. G. H. Bryan on electro-magnetic induction in plane, cylindrical and spherical current sheets, and its representation by moving trails of images, was read by Mr. Elder. The phenomena of induction in a cylindrical conducting sheet in a two-dimensional field, and of induction in a spherical sheet in any field due to the generation or motion of poles, magnets, or currents, in the presence of the sheet, can be represented by moving trails of images which are but slightly more complicated than the well-known trails of images in a plane sheet. The images, representing the potentials of the induced currents on the two sides, start from the source of disturbance and its inverse point, and move normally away from the surface of the sphere and cylinder, with velocity varying directly as the disturbance. At the surface of the sheet this velocity becomes equal to the corresponding velocity for a plane sheet. The images are in most cases similar in nature to the inducing source of disturbance, and their intensities are found, in every case, to vary as a power of the distance from the centre. The images due to the sudden generation of a magnetic pole in the presence of a spherical sheet are, however, analogous to the hydro-dynamical image of a source in a sphere. Dr. S. P. Thompson said the method and the results obtained would find useful application in the solution of many allied problems.—The President proposed a vote of thanks to the author; the meeting was then adjourned until Saturday, February 26, on which occasion the Physical Society will visit Eton College. [Fellows are informed that a train leaves Paddington for Windsor at 2.25 p.m. This arrives in time for the meeting, which is at 4 p.m.]

Zoological Society, February 1.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—Mr. Oldfield Thomas exhibited the skull of a giraffe from the Niger region, which had been shot by the late Lieut. R. H. McCorquodale, and presented to the British Museum by his brother, Mr. W. Hume McCorquodale. No giraffes had previously been received from this region, and as the skull proved to differ from that of the typical species in its greater size, longer muzzle, and more divergent horns, it was considered to represent a special subspecies, for which the name of *Giraffa camelopardalis peralta* was suggested.—Mr. Sclater exhibited some photographs of giraffes in order to show the differences in markings between the two forms *Giraffa camelopardalis typica* and *G. c. capensis*.—A letter was read from Mr. J. Graham Kerr, containing notes on the habits of the Paraguayan Lepidosiren, as observed by Mr. R. J. Hunt. It was shown that during the dry season it retired into burrows like its African relative *Protopterus*.—Mr. G. A. Boulenger, F.R.S., gave an account of the fishes collected by Dr. J. Bach in the Rio Jurua, Brazil. Fifty-one species were enumerated, of which nine were described as new.—Mr. F. E. Beddard, F.R.S., read a paper on the anatomy of an Australian cuckoo, *Scythrops novæ-hollandiæ*, which he was disposed to regard as being more nearly allied to *Eudynamys* than to any other form of the Cuculidæ.—Dr. A. G. Butler read a paper on a collection of Lepidoptera made by Mr. F. V. Kirby, chiefly in Portuguese East Africa. Ninety-two species were enumerated, of which one (*Euralia kirbyi*) was described as new. The paper also contained the description of a new species of *Cyclopides*, viz. *Cyclopides carsoni*, from Fwambo, collected by Mr. A. Carson.—A communication from Dr. N. H. Alcock, on the vascular system of the *Chiroptera*, was read by Prof. Howes. The anatomy of the vascular system of *Pteropus medius* was described and shown in its general plan to resemble in many respects that occurring in the Rodentia, and observations of a comparative nature were added on the pleuræ, pericardium, and lungs. A summary of the literature upon the *Chiroptera* was also included in the paper.

Entomological Society, February 2.—Mr. G. H. Verrall, Vice-President, in the chair.—The Secretary read a letter from Mr. A. D. Michael asking if any entomologists, who might find insects attacked by mites (*Acari*) among their disused boxes, would be willing to send him such insects, with the mites still on them or accompanying them, or at least, the mites themselves, with the name of the insect given in all cases, for the purpose of his forthcoming monograph of the Tyroglyphidæ.—Mr. J. W. Tutt showed a fine series of forms of *Hemerophila abruptaria*, Thunb., captured and bred by Mr. W. S. Pearce at Holloway, varying from the normal colour, through mahogany-brown to dark fuscous, some of the specimens of the second brood showing a purplish hue. One gynandromorphous example was shown, with the wings and right antenna of the female type, the left antenna being strongly pectinated. He also exhibited two specimens of *Dianthœcia luteago*, bred by the Rev. F. Lowe, from larvæ obtained in Guernsey, and of a very distinct character, having a tendency to the ochreous coloration of the type form, but being differently marked.—On behalf of Mr. Heyne, Mr. Jacoby exhibited a series of temperature-varieties of Lepidoptera.—Mr. G. H. Carpenter read a paper by himself and the Rev. W. F. Johnson on the larva of *Pelophila borealis*, describing its structure and life-history. On the larval characters the species, hitherto considered as of doubtful relationship, was regarded as being closely allied to *Elaphrus*.—Papers were communicated by Mr. F. D. Godman, F.R.S., and Mr. O. Salvin, F.R.S., on new species of American Rhopalocera, and by Mr. M. Jacoby, on some phytophagous Coleoptera (Eumolpidæ) from the Islands of Mauritius and Réunion.

Chemical Society, February 3.—Prof. Dewar, President, in the chair.—The following papers were read:—The volumetric estimation of sodium, by H. J. H. Fenton. Sodium dihydroxytartrate is very sparingly soluble in water at 0° and the solubility in presence of excess of a dihydroxytartrate is practically negligible; since dihydroxytartaric acid is readily oxidised by permanganate in sulphuric acid solution, the formation of the sodium salt affords a simple and accurate method of estimating the metal.—The atomic weight of boron, by F. P. Armitage. From determinations of the water of crystallisation in borax, $Na_2B_4O_7$, H_2O, the atomic weight of boron is calculated as 10·928.—Rate of escape of ammonia from aqueous solution, by E. P. Perman. After drawing a volume V of air through a dilute solution of ammonia at a uniform rate, the amount q of ammonia left in solution is $\log q = a - bV$, where a and b are constants; with variable temperature t, $\log b = \alpha + \beta t$, α and β being constants.—On the dissociation of potassium platinichloride in dilute solution; and the production of platinum monochloride, by E. Sonstadt. Potassium platinichloride, in a 0·1 per cent. aqueous solution, is scarcely changed on heating; in a 0·01 per cent. solution platinum monochloride is gradually precipitated on heating, in accordance with the equations (1) $K_2PtCl_6 = 2KCl + PtCl_4$; and (2) $2PtCl_4 + 6H_2O = 2PtCl + 6HCl + 3H_2O_2$.—Effect of the mono-, di- and tri-chloracetyl groups on the rotatory power of methylic and ethylic glycerates and tartrates, by P. Frankland and T. S. Patterson. In order to ascertain the rotatory effect of the halogens when attached at a point in the molecule remote from the asymmetric carbon atom, the authors have examined the mono-, di- and tri-chloracetyl derivatives of the methylic and ethylic tartrates and glycerates; tables of the optical data are given.—The rotation of ethylic and methylic dimonochloracetyltartrates, by P. Frankland and A. Turnbull.

MANCHESTER.

Literary and Philosophical Society, January 25.—Mr. J. Cosmo Melvill, President, in the chair.—Mr. Louis Schwabe was elected an ordinary member of the Society.—The President referred to the loss sustained by the Society through the death of Mr. Thomas Ashton, who, since the death of Mr. James Heywood, was the "Father" of the Society, having been elected in 1837.—Mr. J. J. Ashworth called attention to a paper by Mr. J. Smith, in vol. xxi. of the Society's "Memoirs" (1859) on the origin of colours and the theory of light, in which is given a complete description of the colour phenomena seen when a black and white disc is rapidly rotated. As the phenomena have been to some extent re-discovered during the past few years, and have attracted considerable interest, he thought it advisable to direct attention to a paper which appeared to have been forgotten, in which the subject is treated with great thoroughness.—*Apropos* of an inquiry at a recent meeting of the Society, as to the origin of wheat, the President exhibited specimens of *Ægilops*, *Triticum*, and *Agropyrum* from his herbarium. Mention was made of a grass, *Ægilops ovata*, L., which was declared by a French botanist some fifty years ago to become wheat on being cultivated, and subsequent experiments appeared to confirm this statement. The opinion generally held by botanists now, however, is that in all probability wheat had its origin in *Triticum monococcum*, L., a plant found in Asia Minor, Mesopotamia and Greece.—Mr. Melvill afterwards communicated a paper by Mr. Peter Cameron entitled "Hymenoptera Orientalia, or Contributions to a Knowledge of the Hymenoptera of the Oriental Zoological Region," part vii.

February 8.—Mr. J. Cosmo Melvill, President, in the chair.—Mr. Brothers exhibited and described the latest form of Mr. F. E. Ives' photo-chromoscope, called the "Krōmskōp." Stereoscopic photographs were shown in which the various objects, when viewed through the arrangement of red, blue, and green glasses, were seen in all the colours of nature-groups of flowers, landscapes, &c., being thus realistically reproduced.—On the collision of two explosion-waves, by Messrs. R. H. Jones and J. Bower. This paper was a description of experiments carried out in the research laboratories of Owens College to examine whether there was any increase of pressure on the collision of two explosion-waves. This was shown to be the case, both by direct hydraulic tests of the tubing used and by photographs of the explosions. It was also argued that the increased luminosity at the point of collision and the increased speed of the reflected wave from the point of collision above that of reflection from a hard surface established the fact of greater pressure.

PARIS.

Academy of Sciences, February 7.—M. Wolf in the chair.—The President announced to the Academy the death of M. Jean Albert Gauthier-Villars.—Histological mechanism of cicatrisation; immediate synaptic reunion, by M. L. Ranvier. If two parallel incisions of equal length are made in the cornea of the rabbit, one going only a third to a half through the membrane, the other penetrating right through into the chamber behind, the latter heals more quickly than the simple wound. These effects are due to the part played by fibrin in cicatrisation.—On the development of real non-analytical functions, by M. P. Painlevé.—Transparency of bismuth in a magnetic field, by M. H. Buisson. The electromagnetic theory of light requires a relation between the transparency and electrical resistance of a body. By placing a thin sheet of bismuth in an intense field caused by an electromagnet, it is possible to cause sudden variations in the resistance of the plate. Since not the slightest variation in the intensity of the transmitted light could be detected under these conditions, the author concludes that the conductivity which intervenes in luminous phenomena is probably of a different order to that ordinarily measured.—Cycles of magnetic torsion and the residual torsion of soft iron, by M. G. Moreau.—On a method of comparing curves of torsion, by M. H. Bouasse.—Transformation of the X-rays by transmission, by M. G. Sagnac. A continuation of preceding work on the properties of the secondary rays, or rays emitted by bodies struck by the X-rays.—On photographic development, by M. R. Colson.—On the melting points of gold and silver, by M. Daniel Berthelot. The metals in the form of wire were heated in the furnace described in a previous paper, and the temperature of fusion measured by a platinum-iridium thermo-couple, the latter being standardised in place by the interference method of air thermometry previously described. The temperatures found were 962° C. for silver and 1064° for gold.—Determination of the density of gases upon very small volumes, by M. Th. Schlœsing, jun. (see p. 374).—On the correlation between reduction by nascent hydrogen, electrolysis, and photolysis of carbonic acid, by M. A. Bach. The reduction of a solution of carbon dioxide in water by hydrogenised palladium gave rise to some formic aldehyde, the latter being identified by conversion into methylene-aniline and hexamethylenetetramine. The electrolytic reduction of carbon dioxide is shown to be parallel with the reduction by solar radiation.—On the aromatic urethanes of conicine, by MM. P. Cazeneuve and Moreau,—New colour reaction of phenylhydrazine, by M. Louis Simon. The solution of the hydrazine is warmed with a little aqueous trimethylamine, some drops of a solution of nitroprussiate of soda added, and then concentrated potash. A blue coloration results which allows of the detection of one part of phenylhydrazine in 50,000 of water.—On the influence of the frequency of the movements and of the weights sustained upon the maximum power of muscle under regular treatment, by MM. André Broca and Charles Richet.—On the development of the conjunctive fibrilla, by M. P. A. Zachariadès.—On the constitution of cannel coal, by M. B. Renault.—On the polymorphism of fluorspar, by M. F. Wallerant.

DIARY OF SOCIETIES.

THURSDAY, February 17.

Royal Society, at 4.30.—On the Connection between the Electrical Properties and the Chemical Composition of Different Kinds of Glass: Prof. A. Gray, F.R.S., and Prof. J. J. Dobbie.—On the Magnetic Deformation of Nickel: Dr. E. Taylor Jones.—Upon the Structure and Development of the Enamel of Elasmobranch Fishes: C. S. Tomes, F.R.S.—On Artificial Temporary Colour-Blindness, with an Examination of the Colour Sensations of 109 Persons: G. J. Burch.—Contributions to the Mathematical Theory of Evolution. On the Inheritance of the Cephalic Index: Cicely Fawcett, and Prof. K. Pearson, F.R.S.

Royal Institution, at 3.—Some Italian Pictures at the National Gallery: Dr. Jean Paul Richter.

Society of Arts (Imperial Institute), at 4.30.—The Plague in Bombay: Dr. Herbert Mills Birdwood.

Linnean Society, at 8.—On the Genus Arenaria: F. N. Williams.—On the Histology of the Salivary and other Glands of the *Colubridæ*: G. S. West.

Chemical Society, at 8.—Some Lecture Experiments: J. Tudor Cundall.—Observations on the Influence of the Silent Discharge of Electricity on Atmospheric Air: W. A. Shenstone and W. T. Evans.

FRIDAY, February 18.

Royal Institution, at 9.—A Yorkshire Moor: Prof. L. C. Miall, F.R.S.

Geological Society, at 3.—Annual General Meeting.

Epidemiological Society, at 8.30.—The Relationship of Variations of the Ground-Water Level to the Incidence and Seasonal Distribution of Malarial Fevers in India: Surgeon-Captain Leonard Rogers.

SATURDAY, February 19.

Royal Institution, at 3.—The Structure of Instrumental Music: William H. Hadow.

MONDAY, February 21.

Imperial Institute, at 8.30.—The Nile and its Tributaries: Colonel C. M. Watson, R.E., C.M.G.

Society of Arts, at 8.—The Principles of Design in Form: Hugh Stannus.

Victoria Institute, at 4.30.—Purpose in Nature: Dr. W. Kidd.

TUESDAY, February 22.

Royal Institution, at 3.—The Simplest Living Things: Prof. E. Ray Lankester, F.R.S.

Anthropological Institute, at 8.30.—Ethnographical Notes on the Murray Islands, Torres Straits: Rev. Archibald E. Hunt.—There will be exhibited two Tattooed Heads carved in Kauri Gum from New Zealand, lent by Edge Partington; and a Collection of Objects obtained during the Recent Exploration of a Cairn in Breconshire, lent by T. C. Cantrill.

Institution of Civil Engineers, at 8.—The Theory, Design, and Practical Working of Alternate-Current Motors: Llewelyn B. Atkinson.—Dublin Electric Tramways: H. F. Parshall.

WEDNESDAY, February 23.

Society of Arts, at 8.—Children's Sight: R. Brudenell Carter.

THURSDAY, February 24.

Royal Society, at 4.30.—Meeting for Discussion.—Subject: The Scientific Advantages of an Antarctic Expedition. The Discussion will be opened by Dr. John Murray, F.R.S.

Institution of Electrical Engineers, at 8.—On the Manufacture of Lamps and other Apparatus for 200 volts Circuits: G. Binswanger Byng.

FRIDAY, February 25.

Royal Institution, at 9.—The Theory of Colour Vision applied to Modern Colour Photography: Captain W. de W. Abney, C.B., F.R.S.

Institution of Civil Engineers, at 8.—The Problem of Train Resistance: C. E. Wolff.

SATURDAY, February 26.

Royal Institution, at 3.—The Structure of Instrumental Music: W. H. Hadow.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—The Arrangement of Atoms in Space: J. H. van 't Hoff, 2nd edition, translated and edited by A. Eiloart (Longmans).—On Laboratory Arts: Prof. R. Threlfall (Macmillan).—Motion: its Origin and Conservation: Rev. Dr. W. McDonald (Dublin, Browne).—Calendar, &c., of the Department of Science and Art, 1898 (Eyre).—Evolutional Ethics and Animal Psychology: E. P. Evans (Heinemann).—The Flora of Berkshire: G. C. Druce (Oxford, Clarendon Press).—Researches on Tuberculosis: Dr. A. Ransome (Smith, Elder).—Pasteur: Prof. and Mrs. P. Frankland (Cassell).—Lehrbuch der Entwickelungsgeschichte des Menschen: Dr. J. Kollmann (Jena, Fischer).—Organographie der Pflanzen: Dr. K. Goebel, Erster Teil (Jena, Fischer).—Das Optische Drehungsvermögen: Dr. H. Landolt, Zweite Auflage (Braunschweig, Vieweg).—Die Gattung Cyclamen L.: Dr. F. Hildebrand (Jena, Fischer).

Pamphlets.—Museum Handbooks; Catalogue of the Hadfield Collection of Shells from the Loyalty Islands, Parts 2 and 3 (Manchester, Cornish).—A Visit to Giessen: Prof. Senier (Dublin, Ponsonby).

Serials.—Physical Review, November, December, and January (Macmillan).—American Journal of Psychology, January (Worcester, Mass.).—Observatory, February (Taylor).—Bulletin de la Société Impériale des Naturalistes de Moscou, 1897, No. 2 (Moscou).—Geographical Journal, February (Stanford).—Boletim do Museu Paraense, &c., Vol. 2, No. 2 (Pará, Brazil).—Quarterly Journal of Microscopical Science, January (Churchill).—Engineering Magazine, February (222 Strand).—Atlantic Monthly, February (Gay).—Zeitschrift für Physikalisches Chemie, xxv. Band, 1 Heft (Leipzig, Engelmann).—Annales de l'Electrobiologie, &c., No. 1 (Paris, Alcan).—Memorias y Revista de la Sociedad Cientifica, Tomo x. Nos. 5-12 (Mexico).—Memoirs of the Boston Society of Natural History, Vol. v. No. 3 (Boston, Mass.).—An Illustrated Manual of British Birds: H. Saunders, 2nd edition, Part 4 (Gurney).—Journal of the Institution of Electrical Engineers, Feburary (Spon).—Memoirs and Proceedings of the Manchester Literary and Philosophical Society, Vol. 42, Part 1 (Manchester).—American Journal of Science, February (Newhaven).—Among British Birds in their Nesting Haunts: O. A. J. Lee, Part 9 (Edinburgh, Douglas).—The West Australian Settler's Guide and Farmer's Handbook, Part 5 (Perth, W.A., Wigg).

THE MAGNETIC CIRCUIT.

The Magnetic Circuit. By H. du Bois, Ph.D. Translated by E. Atkinson, Ph.D. Pp. xviii + 362. (London: Longmans, Green, and Co., 1896.)

NO one is better fitted than Dr. du Bois to write a treatise on the magnetic circuit. He is well known for his experimental investigations in magnetism, and abstract magnetic theory is clearer and more comprehensive for his restatement of its main propositions. His German treatise, "Die Magnetische Kreise," published some five years ago, attracted considerable attention in this country. It gave in reasonable compass an excellent account of magnetic theory, methods of magnetic measurement, and of recent magnetic research, in which Dr. du Bois' own contributions to knowledge formed an important part, not merely on account of their intrinsic value, but of their clear and first-hand and withal modest statement.

A translation of this book, made by Dr. Atkinson with the assistance and revision of the author, and one or two other experts in the subject, was published in 1896, and was thoroughly welcomed by the already considerable and continually increasing number of experimentalists in electricity and magnetism. Some apology for so late a review of so important a work is necessary, and this is now offered by the reviewer, whose fault it has been that an account of it has not long before now appeared in NATURE. Still "good wine needs no bush,' and the work of Dr. du Bois carries its own guarantee of excellence on the face of it.

The book begins with a very valuable summary of magnetic quantities and conceptions, in which the fundamental ideas of magnetic force, magnetic induction, intensity of magnetisation, permeability and susceptibility, &c., are fully explained, and the graphical representation of their values for actual cases is fully illustrated by curves of induction and magnetisation obtained for actual specimens of iron and steel.

The question of the effects of the ends of a bar of magnetised iron or steel, or of a narrow crevasse or joint between two parts of a bar or ring, is taken up towards the end of Chapter i., and is continued in Chapter ii. Ewing's representation of the effect of the cut, by a shearing of the curve of magnetisation for the uncut bar or ring, is given, and illustrated, as before, by the results of actual investigations—mostly those of Ewing himself. The effect of a cut leads to a further discussion of that of an end, and thence to a discussion of Coulomb's law for the distance action of a magnetic pole, and of the field at a point due to a pair of equal and opposite "point-charges" of magnetic matter.

Of course this action at a distance is what is actually observed, and there is an advantage in starting with what are the immediate results of experience. Still, if the book, as no doubt it will, should pass soon to a new edition, we should like to see some account of a more "mediumistic" view of the matter included. It is possible, and in connection with the electromagnetic theory of light it is very desirable, to consider magnetic force and magnetic induction not only as both existing as directed quantities at every point of a magnetised body, but at every point of the electromagnetic field, in ether or other "interferric" material, as well as in iron itself. With electric induction and electric intensity also introduced as the analogues of the magnetic quantities, with k for the electric inductivity, and μ for the magnetic inductivity of the medium, whatever it may be, all difficulties as to units disappear if k and μ are regarded as depending upon real physical properties of the medium which, if fully known, would determine the dimensions of these quantities, and $1/k\mu$ is seen in a natural way to be the square of the velocity of propagation. The serious difficulties which students feel with respect to this matter, and which are only apparently overcome by an unsatisfactory process, are entirely avoided.

In Chapters iii. and iv. we have an Outline of the Theory of Rigid Magnets, and a discussion of Magnetic Intensity and Magnetic Induction. The account of rigid magnetism and of induction here given is based in the main on that source of all theory on the subject, Lord Kelvin's Mathematical Theory of Magnetism, and on the digest of this part of the subject given in Maxwell's great treatise, and includes most of the more valuable results obtained by Kirchhoff, and by later writers who have commented on or developed the theoretical principles laid down by these masters. Here Dr. du Bois has himself done good service. He has given solutions of important problems of induction, and generally, as stated above, in certain points improved the presentment of theory; work of which English readers now reap the full advantage.

A chapter on the Magnetisation of Closed and of Radially Divided Toroids, which is divided into two parts—(*a*) Theoretical; (*b*) Experimental—closes the first part of the treatise. This chapter is exceedingly important. Kirchhoff's theory of the magnetisation of a solid of revolution is given, and its results for rings of rectangular and circular section are deduced. This investigation of Kirchhoff's gave rise to the experimental investigations of Stoletow and Rowland, the results of which have only confirmed its correctness.

Results are next deduced for a radially divided ring, which are fully illustrated in the experimental investigations described later. Thus we have the subject of leakage of magnetic induction introduced and clearly discussed and illustrated. The great practical importance of this part of the subject will be obvious when its application to dynamo machines is considered, and a large part of the experimental investigations which have been carried out have had to do with the question of the distribution of tubes of induction in or near more or less narrow gaps in what may be regarded as closed circuits or rings of iron.

The great importance of having a magnetic circuit nearly closed was recognised by Faraday, and was more or less present to the minds of makers of magnets, both permanent and electro, down to the beginning of the present active manufacture, on a large commercial scale, of dynamo machines.

Then it was that Hopkinson came forward with his explicit statement of the laws of the magnetic circuit, and their application to the construction of the field magnets of dynamos, a piece of work for which practical science owes him a heavy debt. The magnetic circuit, and the mode of testing the performance of dynamo machines by means of characteristic curves, which themselves give valuable information regarding the magnetisation of the circuit, really did for the dynamo machine very much what practical thermodynamics and the indicator did for the steam-engine.

After an account of the General Properties of Magnetic Circuits, Dr. du Bois proceeds in his Chapter vii. to a discussion of the Analogy of the Magnetic Circuit with other Circuits. Here the author, as we think very properly, condemns the use of the term "Ohm's Law" to express the fact that magneto-motive force in the circuit divided by the magnetic reluctance is equal to the flux of induction in the circuit. This, it has always appeared to us, is using the term "Ohm's Law" to describe what is a mere result of definition. The equality of the magneto-motive force multiplied by the permeance (permeance = 1/reluctance) of the circuit to the flux of induction is a result of definitions of induction and field intensity, and to thus use it is to introduce into magnetics the confusion which many have fallen into with regard to the law of Ohm in voltaic circuits. In the latter case, the law, properly speaking, expresses the proportionality of the current in a conductor to the difference of potential between two points in the conductor near its ends when the conductor is not the seat of any internal electromotive force. This result has no counterpart in magnetic circuits, and no "Ohm's Law" holds there.

In Chapter viii. the Magnetic Circuits of Dynamos or Electromotors is dealt with, the work of the brothers Hopkinson, the empirical formulæ for the magnetisation curves of such machines given by Frölich and others are all described, and the application of all this thoroughly practical theoretical discussion is focussed on the construction and arrangement of the field-magnets and armature of the machine.

We are immediately carried on in a natural sequence to magnetic cycles and hysteresis, and the immensely important researches on the magnetic properties of iron carried out by Ewing and others. The results in this field are, however, before all our readers specially interested in the subject, and the subject is so large and so full of detail, that we cannot with any advantage continue our sketch of the contents of the book.

The magnetic circuits of electromagnets, containing an account of the devices used by Ewing and the author to obtain very intense fields, and of methods of measuring such fields, is given in Chapters ix. and x. Up to about fifteen years ago determinations of field intensities had been confined to measurements of the earth's field-intensity or intensities of like magnitude, and a paper (*Philosophical Magazine*, 1882) by the present writer, describing methods which were in use in the Glasgow University Physical Laboratory, contained perhaps the first published statement of how the field between the poles of a powerful electromagnet could be quickly and accurately measured.

In this connection also we have one of the author's notable contributions to magnetics, in his account of the researches which he carried out at Berlin on the magneto-optical method of measuring intense fields.

Here we must conclude our review of a most fascinating book. It cannot be praised too highly as a piece of work sound from every point of view, and tending to the advancement of knowledge. Dr. Atkinson and his colleagues have performed their work of rendering the book into English very carefully indeed, and on the whole the version reads like a book originally written, and well written, in English. Only in one or two places have we found, in a fairly extensive comparison of the German and English, that the sense has not been exactly caught. For example, at p. 340 a method of investigation there referred to is rather hardly treated by being described as "circuitous." The German "umständlich" ought here to be rendered by "circumstantial."

A. GRAY.

AUDUBON.

Audubon and his Journals. By Maria R. Audubon. With zoological and other notes by Elliott Coues. 8vo. Two vols. Vol. I., pp. xiv + 532; Vol. II., pp. viii + 554. Portraits, copies of diplomas, photogravures, &c. (New York: Charles Scribner's Sons, 1897.)

NATURALISTS and many who are not naturalists will find this an entertaining book. It gives in great detail the incidents of certain years of Audubon's life, years in which he was carrying on his work in the field, or else meeting every day men who are still noteworthy. The book is founded upon unpublished journals and letters, of which parts are given at length. All has been corrected by recollections handed down in the family, and the zoological information has been revised by Dr. Elliott Coues. A summary of the naturalist's life is prefixed. We have now a full and lively account of what is most memorable in the life of Audubon.

Some readers who are not naturalists will turn with curiosity to the passages in which mention is made of places which are now populous American cities, but which, when Audubon dwelt there, or passed through, were backwoods settlements. Others will be glad to note small particulars concerning the naturalists, merchants, and men of letters whom Audubon saw during his visit to Europe in 1826–29—Cuvier, Bewick, Jameson, Selby, Jardine, Rathbone and Roscoe. Others again will study the character and methods of a man, who partly by real merit, and partly by the good-luck of becoming known to men who could write, has been widely accepted as a typical naturalist. Some of us can hardly remember the time when we had not heard of Audubon as the man who faced all dangers and fatigues, caring nothing for comfort or profit, if only he could learn more and more of the wild creatures which fly from the face of man. There is matter here for readers of very different kinds, and all should thank those who have rescued so many old papers, and arranged them so carefully.

Audubon was a real naturalist, if ever there was one. He had the passion for observing and drawing birds almost as a gift of nature. As a boy and young man he was fit for nothing else, but the responsibility which a family brings made him in middle life a sensible man of business. He was never a man of science. He never received from others, nor gave himself any kind of training in scientific method; he never studied the anatomy of birds or systems of classification; above all, he never put questions of the slightest scientific interest. It was enough for him to draw his birds as they looked when alive, and now and then to note some curious detail in their mode of life. His less famous helper, MacGillivray, was far better furnished and far more productive. Audubon's "Birds of America" has great artistic merit, but less scientific value than a good series of photographs from life.

Audubon's career is now revealed to us more fully and more pleasantly than in any earlier account. He was born of French parents at Mandeville, on Lake Ponchartrain, somewhere about 1780. His first seventeen years were spent almost altogether in France, and he showed his turn of mind by making 200 drawings of the birds of France. Then he was sent out to Philadelphia, where his father had landed property. After another two years in France he came back to America, which henceforth he always claimed as his fatherland. At first young Audubon lived like a young gentleman of property, hunting, fishing, shooting, skating, but drawing birds too. He was a bit of a dandy in those days, and a favourite with young ladies. He went into business, married, and should according to all expectation have settled down as a money-making American. But he was intent upon birds and not upon money. He was easily diverted from a business-journey by a glimpse of a new bird, and was regularly cheated by his partners, agents, employers and customers. He complained that one of his partners cared only for money; the partner on his side complained that Audubon had no turn for commerce, and was continually in the forest. The advantages with which he started were soon lost, and in a few years we find him roving about in America, giving drawing-lessons, music-lessons, dancing-lessons, drawing portraits, but always adding to his portfolio of birds, and always studying how to make his delineations more life-like. The hope of publishing his great collection gradually became more definite. In 1826, being then near fifty years old, he came over to Europe to get subscriptions and engage draughtsmen. His diary shows him to us as sobered down by this time to a modest, careful man, minding his chances, and thoughtful for his wife and children. His success in publishing the "Birds of America," his later ventures, his expeditions to Labrador, Florida and the Missouri River, as well as his charming family life, are all described in the book before us. In 1847 his faculties began to give way, and he died in 1851.

The "Birds of America" has maintained its reputation, in spite of its enormous bulk, its costliness, and its want of scientific utility. It is now a luxury, only to be possessed by the wealthy, and very seldom enjoyed even by them, an unprofitable jewel in comparison with the homely tools which the working ornithologist requires. To have published a book which very few men can afford to buy, gives a certain kind of distinction. Audubon has better claims upon our attention than this, but the ever-rising price of his "Birds of America" has helped his fame.

One thing in the journals moves our indignation, but it will hardly excite remark among the naturalists of to-day; we mean the profuse and needless slaughter of wild animals, which fills almost every page of the journals. Audubon rises in the morning, snatches his gun, shoots everything that shows itself, and then sits down to draw his victims. Some naturalists look upon all this bloodshed and torture as inevitable, or even enjoyable. That is the way to get together a museum of dried skins or a portfolio of drawings; it is not the way to solve scientific questions, nor to gain real insight into the works of nature.

L. C. M.

SEWER GAS AND HEALTH.

Sewer Gas, and its Influence upon Health. Treatise by H. A. Roechling, C.E. Pp. 224. (London: Biggs and Co., 1898.)

THERE is hardly a Corporation in the United Kingdom, we venture to say, to whose members sewer gas is not a hideous nightmare. It is the legacy of a bygone generation of hygienic enthusiasts, and is likely to prove the *bête noir* of many a succeeding generation of despairing sanitarians. Despite the brilliant achievements in the domain of hygiene of which the present century can justly be proud, the sewerage problem remains still a gordian knot the disentanglement of which seems as far off as ever.

Public opinion has swayed backwards and forwards, immense sums of money have been expended in what may be designated as vast hygienic experiments, sewers have been laid and relaid, ventilators introduced and abolished, and innumerable devices invented and applied in the hope of effectually getting rid of this mysterious and subtle influence in our midst.

Mr. Roechling in the above volume has added one more to the many indictments which have been published against sewer gas. These indictments are necessarily of a somewhat vague description, founded, as they must be, more on personal conviction than on strictly scientific facts; for our precise knowledge of the character and properties of this gas is at present so extremely limited, that we are frequently reduced to the manipulation of mortality statistics for a basis of attack. We must not, therefore, approach this book in the hope of finding a pyramid of new facts, for we may have to be satisfied with hardly a molehill, but we may recommend it as containing a useful summary of the circumstantial evidence which can be adduced against sewer gas.

The arrangement of the material, however, leaves much to be desired, and the writer is needlessly verbose. Considerably more than half the book is taken up with appendices, to which the preceding portion of the book has constant reference, and these appendices would be very much the better for judicious pruning. Page after page, for example, are devoted to detailed reports of cases of supposed poisoning through sewer gas; over twenty pages are occupied with reporting in full the legal proceedings connected with a case of blood-poisoning, &c. All this, no doubt, serves to swell the size, but it certainly does not increase the value of the volume.

As an example of the justifiably perplexed condition of some of our public authorities on the question of sewer gas, we may cite the case of Leicester as mentioned by the author. Up to the year 1881 the sewers of this city were in a very foul condition, and were not ventilated in any way, and the typhoid death-rate was as high as 31·2 per 100,000. In 1881, however, the Town Council decided to open up the sewers, thoroughly cleanse them, and ventilate them by open covers at street level. Subsequent to this, and up to the year 1886 the typhoid death-rate showed a most remarkable decrease, falling during this period at its lowest to 16·3 per 100,000. Yielding, however, to the pressure of numerous public complaints about the obnoxious smells rising from the sewers in the various thoroughfares of the town, the Sanitary Committee decided in 1886 to close the open street ventilators, and to erect in their place cast-iron pipes up the sides of houses wherever the necessary permission of the house-owners could be obtained.

Since 1886, also, improvements have been made in the sewerage system of the town, for the old and small main sewers have been replaced by larger and better constructed ones at a cost of nearly 200,000*l.*; but in spite of this and other sanitary improvements, the typhoid death-rate has actually risen in Leicester during this latter period. *Felix qui potuit rerum cognoscere causas!*

It must indeed be frankly admitted that our knowledge of the conditions—and there may be many factors, which determine outbreaks of epidemic disease—is at present in some respects hopelessly inadequate. No more conclusive example of this is to be found than is presented by the diphtheria epidemic which has taken such a firm hold of London, and which has also manifested itself in various other parts of the country, and, despite all the boasted hygienic enlightenment of the closing years of the century, pursues its triumphant course practically unchecked.

Sewer gas may be charged with a great deal, but we also know that other factors—as, for example, infected water and milk—are also heavily weighted with responsibility in the dissemination of disease, and that to shift the whole burden of a particular epidemic upon any one single factor becomes the more unreasonable the wider our scientific horizon is extended.

G. C. FRANKLAND.

OUR BOOK SHELF.

Chambers's Algebra for Schools. By William Thomson, M.A., B.Sc., F.R.S.E. (London: W. and R. Chambers, 1898.)

THIS is a plainly written and well-arranged book of secondary grade, quite worthy of the crucial test which only practical teachers can apply. Among its praiseworthy features may be mentioned the attention paid to degree, homogeneity, and symmetry; the early introduction of the method of detached coefficients; and the elementary discussion of graphs. The chapter on indices is more satisfactory than is usually the case in works of this kind; on the other hand the chapter on surds is disappointingly conventional, and that on logarithms might certainly be revised with advantage. All logarithmic calculations ought to be printed in the form in which a computer would write them down on paper; explanations, of course, may be added when necessary.

The chapter on the binomial theorem for any exponent is not satisfactory: it would be much better simply to state the conditions under which the theorem is true, and to give some numerical examples to illustrate the use of it for purposes of approximate calculation.

The examples are numerous, and there is, on the whole, a refreshing absence of those fantastic absurdities which are never found except in text-books and examination papers. In the examples on variation, illustrations derived from physics might very well have been inserted: the same thing may be said about the examples on equations.

It is probably useless to protest against the method of solving quadratics by completing the square; like the Imperial system of weights and measures, it has become a national fetish, and its cult is proof against all the arguments of common sense.

G. B. M.

Die Kraft und Materie im Raume. Grundlage einer neuen Schöpfungstheorie. By A. Turner. Fifth edition. Pp. xxiv + 407, and 20 plates. (Leipzig: Theod. Thomas, 1897.)

IN his preface to the present edition of this work the author remarks:—

"We have given positive proofs of the untenability and the imaginary foundation upon which rest the hypotheses which have for their subject-matter the theory of vibration of a cosmic ether, whether these relate to light, heat, or to the artificial terms under the ægis of 'the conversion of work into heat, energy into electricity, &c.,' in short the greater part of the hypotheses which form the foundation and chief support of the privileged sciences of to-day.

"They represent no scientific truths, but, together with the catch-words indicated, serve merely as a cloak for ignorance, their supporters having no suspicion of the nature or true inwardness of the phenomena in question or of their causal connection."

Turning to the body of the work we find, expressed in somewhat similar style, a theory of the universe postulating matter and space as ultimate realities. Matter consists of centres of force attracting or repelling each other when they approach each other within certain limits. Light is the impression made on the optic nerve by radiant matter. The phenomena of heat are due to the repulsion of one substance by another, and so on. At the end of the book 150 theses are printed for the convenience of those who feel impelled to combat the author's views.

The Observer's Atlas of the Heavens. By William Peck, F.R.A.S., F.R.S.E. Charts 30; pp. 32. (London and Edinburgh: Gall and Inglis.)

THIS volume contains catalogues giving information relating to double stars, variable stars, nebulæ, and other celestial bodies, together with thirty star charts in which the positions of nine thousand objects are shown.

The charts include the whole celestial sphere, and are drawn to a large scale, five degrees of a great circle being equal to one inch. They are arranged so that, as far as possible, each constellation is shown complete in itself. The scale of magnitudes is well chosen, the stars appearing with the same relative importance on the charts as in the heavens. The practical value of the atlas would be greatly enhanced, however, if a scale of magnitudes were attached to each chart.

The brighter stars, down to the third magnitude, are shown to a half, and fainter stars to a whole magnitude. To facilitate identification in the various catalogues, either a letter or Flamsteed number is attached to every important star. A commendable feature is the insertion of the various data, from which the charts were compiled, in the form of catalogues of the different celestial bodies. These catalogues will be found very useful, and include such information as the magnitudes of the brighter stars to the nearest tenth, and the positions of stars down to the fourth magnitude, with their Flamsteed and British Association numbers.

Other useful information is included, such as diagrams showing the appearances of over one thousand double stars when near the meridian, and a chart of the moon with an index.

Undoubtedly, this atlas will be found very useful by astronomical observers, especially amateurs, for whose requirements it seems to be particularly designed.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Protective Mimicry and Common Warning Colours.

I HAVE just read with interest Sir George Hampson's criticism of certain supposed examples of protective mimicry. Such outspoken attacks are satisfactory in bringing out the truth one way or the other; and they contrast very favourably with vague expressions of opposition unaccompanied by reasons, and not stated in a manner or on an occasion which would permit reply.

I find from his letter that insufficiently supported conclusions are not confined to those who accept the theories in question. Sir George Hampson described a new geometer (*Abraxas etridoides*) from a single specimen in a private collection, and pointed out its resemblance to a *Teracolus* (*T. etrida*) from the same part of the world. Colonel Swinhoe directed the attention of the President of the Entomological Society to the resemblance, considering that it supported his (the Colonel's) contention that *Teracolus* is a protected genus. From these facts Sir George Hampson draws the remarkable conclusion that Colonel Swinhoe had in all probability never seen the species of *Abraxas* referred to. I give the inference in his own words—"this was quite enough for such an ardent student of mimicry as Colonel Swinhoe to base the statement on, without knowing any more of the species, and probably without ever having seen it, the type being in a private collection." The last reason would be more convincing if it was not followed by the statement—"I have, however, lately received more specimens." If Sir George Hampson, why not Colonel Swinhoe? As a matter of fact, Colonel Swinhoe received several specimens of *Abraxas etridoides* many months before he wrote to the President about them. There is a specimen in the Hope Collection here, presented by him in the early summer of last year.

All this does not affect the theory of mimicry. But the letter goes on to argue that the resemblance cannot be mimetic because the *Abraxas* rests in damp woods, while the *Teracolus* is flying on the plains 6000 feet below; and, furthermore, that the former is protected by distastefulness, while the latter is not. Similar objections are then raised against the supposed mimetic resemblance of Chalcosid moths to Danaine and Papilionine butterflies.

Now I quite agree that these criticisms, and especially that of the special protection of the moths, are destructive of any interpretation of the resemblance based on Bates' theory of protective mimicry. But they do not similarly affect that theory of mimicry (or more accurately common warning [synaposematic] colours) which we owe to Fritz Müller. Being aware of the distasteful qualities of *Abraxas*, I had at once placed the example under the latter category and not under the former.

The Müllerian theory supposes that a common type of appearance among distasteful insects in the same locality acts as a common advertisement to enemies, so that the loss of life which must ensue during the time in which each generation of enemies is being educated to avoid the owners of a particular type of pattern and colouring, is shared between these species instead of being borne by each of them independently.

Prof. Lloyd Morgan's recent experiments on young birds of many species prove that there is no inherited knowledge of suitability or unsuitability for food, but that everything of an appropriate size and at the right distance is pecked at and tested. On the other hand the young birds are extremely quick in learning, and have very retentive memories. Furthermore one unpleasant experience makes them suspicious of other things, and they remember well the appearance of the insect which gave them a disagreeable surprise. Many more such experiments are needed, but taken alone they go far to show that the education of young birds is actually of the kind which is presupposed by Fritz Müller's theory.

And what is true of birds is probably true of other animals as well. My experience with lizards points in the same direction.

Sir George Hampson has previously pointed out that birds sometimes devour *Teracoli*; but I have induced a lizard, by hunger, to eat an *Abraxas*. It is probable that *Teracoli* are, *on the whole*, avoided by birds; and if this is also true of the *Abraxas*, the resemblance may well be advantageous in spite of the difference in habits and the difference of station, even granting that the "good round sum" of 6000 feet is an absolute barrier to the *Teracoli* below and the *Abraxas* above. But future investigation may show that they approach much nearer than this.

The facts brought forward in Sir George Hampson's letter, while, I submit, by no means fatal to the Müllerian theory of mimicry, seem to be entirely destructive of the other suggestions by which the attempt has been made to explain these resemblances—suggestions which depend upon similarity in climatic or other physical or chemical conditions connected with locality.

The last paragraph of the letter demands a word of protest. If insufficient field observations have been made, it is because the observers have thought of other things, and chiefly the amassing of specimens; but it is, in part, due to the extreme difficulty of the observations themselves. And under any circumstances the museum work was necessary for the theory. Mr. Godman, in his presidential address to the Entomological Society, told us that the theory was suggested to Bates as a result of the comparison of specimens at home, although of course his memory of observations in the field was also necessary. The work in the study enabled him to bring under observation at a single time the captures which were separated by great intervals of time and space; and no doubt it was the opportunity thus afforded of taking a broad view of the resemblances as a whole, which enabled him to originate the theory.

It seems strange that a writer whose energetic and successful work has involved so much "matching of specimens in a drawer," should speak of mimicry as "degraded" by such study. It is a necessary and important study for the naming of species as well as the recognition of examples of mimicry, and as such it deserves respectful attention, although it may at times have led to the creation of "museum-made" species on an even larger scale than the manufacture of "museum-made mimicry." The matching of ribbons of uniform colour can hardly be compared with any degree of fairness to the matching of the complex patterns on the wings of Lepidoptera; but in the matching of highly developed specimens of decorative art by the anthropologist, and in the attempt to determine whether the resemblance is due to a common origin, or to accident, or to the mind of man working independently along the same lines, we have problems which present much in common with those confronting the student of mimicry.

In conclusion it may be well to remind those who oppose the theories of mimicry on the ground that the evidence is not demonstrative, that we believe in evolution although we do not see one species growing into another. We believe the theories of mimicry and of common warning colours, not because we have before us demonstrative proof in a complete knowledge of the details of the struggle for existence—it will be very long before we attain to this—but for the same reason that we believe in evolution—because the theory offers an intelligible explanation of a vast number of facts which are unexplained by any other theory as yet brought forward, and especially because it enables us to predict the existence of facts which we can afterwards verify.

EDWARD B. POULTON.

Oxford, February 18.

Oat Smut as an Artist's Pigment.

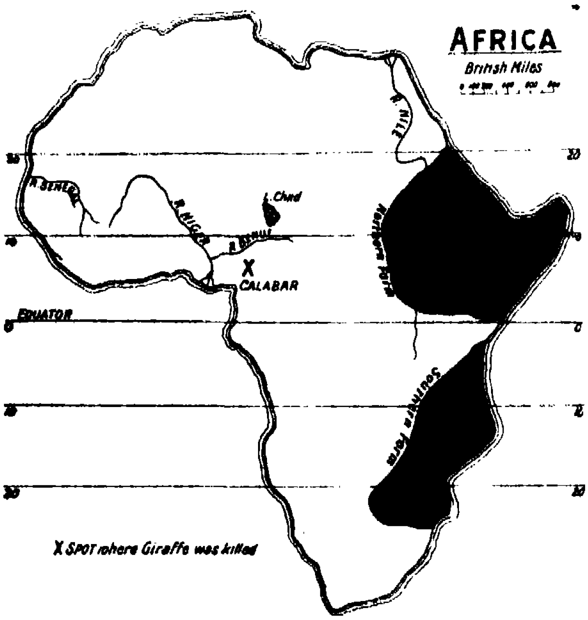
WITH reference to Mr. David Paterson's interesting letter in NATURE for February 17 (p. 364), it may be noted that a copy of an etching from a painting by Berghem, in the Kew Museum, No. 2 (Case 115, No. 200), is drawn with smut of wheat (*Ustilago Tritici*), and that, according to Dietel (*Die Naturlichen Pflanzenfamilien*, Th. I. 1 Abth. p. 6), ladies in Japan are accustomed to use the dark olive-brown spores of *Ustilago esculenta* as a pigment for painting the eyebrows.

H. MARSHALL WARD.

Botanical Laboratory, Cambridge, February 18.

Giraffe from the Niger Territories.

MY brother, the late Lieut. R. H. McCorquodale, of the 3rd Dragoon Guards, while doing special service duty in West Africa, was fortunate enough to kill a very fine giraffe (female). This is a most interesting record, as it is the only specimen that has ever been obtained in these regions. The skull, which was sent home to me, along with a considerable number of heads of antelope, lion, leopard, &c., is now in the British Museum, and Mr. Oldfield Thomas, of that institution, has compared it with the skulls of both the Northern and Southern forms; such marked differences have been noticed, that opinion is in favour of the possibility of its being a new species—for the time being, until it has been more fully worked out, he has made it a special sub-species, and named it *Giraffa camelopardalis peralta.* The giraffe was killed south of the Benue River, north of Calabar. The accompanying map will roughly show the geographical distribution of the two known forms, the haunts of these animals being filled in. Although one or two specimens have been recorded on the eastern shores of Lake Chad, and also on the Senegal River, from 10° N. to 20° S. of the equator no fact is on record of a giraffe having been seen or killed within the degrees mentioned in all that part designated West Africa. The map will show at a glance the immense tracts of country between the habitats of these animals and the spot where this single animal was killed. In a letter I had from Sir George Taubman Goldie, the Governor of the Niger Company, he says: "This is the only giraffe ever known in these regions; I have no doubt there are others, but they have never been seen."



The above facts were mentioned by me at a meeting of the Linnean Society, on the 20th of last month; and Mr. Thomas exhibited the skull at the Zoological Society on the 1st inst., and among some of his remarks stated the skull to be the largest he had ever seen. W. HUME McCORQUODALE.

Abridged Long Division.

HAVING been working on similar lines for some years, I was very much interested in the late Mr. Dodgson's letter on abridged division in NATURE of January 20, and I should like to offer a few observations and to give a variation of the method which appears much simpler. It will be admitted that Mr. Dodgson's plan is of limited application, and rather complicated for general use. There is nothing to hinder the method given below from being universally used, though it may not in all cases be the shortest. It also has the merit, I think, of directness and uniformity.

It is, of course, based on the theorem in geometrical progression.

$$\frac{N}{ar^n \mp m} = \frac{N}{ar^n} \pm \frac{mN}{(ar^n)^2} + \frac{m^2N}{(ar^n)^3} \pm \cdots \frac{m^{n-1}N}{(ar^n)^n},$$

e.g. (1) Divide 246813579 by 989. Here $a = 1$, $r = 10$, $n = 3$, $m = 11$.

```
1000|246813579|
       246813|579 × 11 = 2714943
         2714|943 × 11 = 29865
           29|865 × 11 = 330
             |330
       249558·717 quotient.
```

It will be observed that in multiplying by $m = 11$, we need only use the figures to the left of the line, and if the first figure to the right of the line be > 5, call it one more; thus,

2715 × 11 = 29865, and 29·8 = 30 × 11 = 330.

If extreme accuracy be required, the computer has only to carry the process further.

In this example we need not do so, as the divisor is 1000 throughout.

(2) Divide 975318642 by 3997.

```
4000|975318642|
      243829|6605 × 3 ÷ 4
         182|8722 × 3 ÷ 4
            |1372
      244012·6699 quotient.
```

Remainder in integers

= 8642 - (2 × 4000 - 4012 × 3) = 2678.

The 8642 and 4012 are the $n + 1$ figures of dividend and quotient respectively.

(3) Divide 12345678975312468 by 69993.

```
70000|12345678975312468|
           176366842504|46 × 7 ÷ 7 = × 1
               17636684|25
                   1763|66
                       |17
Quotient   176384480952|5
```

Actual remainder

= 312468 - (2 × 70000 - 80952 × 7) = 39132

retaining only the last $n + 1$ figures.

(4) Divide 975312468 by 7003.

```
7000|975312468|
        139330|353 × 3 ÷ 7
            59|713
Quotient 139270|6
```

Actual remainder 2468 - (0 × 7000 + 9270 × 3) = 4658, retaining only last $n + 1$ figures.

It will be noticed here that we subtract to get the quotient. The reason is evident. We actually divide by 7000 instead of 7003, and therefore the quotient is too great.

If the remainder be known, as *e.g.* in recurring decimals, the following process, published by me some years ago, is shorter than the ordinary method, besides possessing the advantage of *finding its own quotient.*

Divide 85296419765·1 by 9731

```
      973
   41879·2
    1946
   3993·3
   2919
  6107·4
  3892
 9221·5
 4865
52435·6
 5838
84659·7
 6811
7784·8
7784
....
```

The quotient 87654321. It is obtained the reverse of the ordinary way.

This method bears the same reverse relation to ordinary division as the left method does to the right in an ordinary multiplication, *e.g.*

(1)	(1)	(2)	(2)
321	321)241713(753	321	24171·3
753		753	
2247	2247	963	96
	1701		407·5
1605	1605	1605	160
963	963	2247	224·7
241713	963	241713	224
	....		

Anfield Road, Liverpool. ROBT. W. D. CHRISTIE.

Earthquake in North Britain.

IT may be of interest to you to note that on Wednesday, February 16, at about 1.35 p.m., a sharp shock of earthquake was felt here. Houses were shaken, dishes rattled and tumbled, and much alarm was created, though no damage was done. At the time mentioned there was a loud report, as if of a heavy shot fired underground: earth movements—such as would result from violent concussion—immediately followed, lasting for about two seconds; the character of the movements then seemed to alter from vertical to horizontal, the latter being sustained for nearly four seconds. About two minutes after the first report a second was heard, louder and sharper than the first, but no tremors were felt. Judging from the sounds, it would appear that the wave travelled from west to east.

I may state that within recent years several shocks of earthquake have been felt in the district.

Kilsyth, N.B., February 18. JAMES M'CUBBIN.

ON THE USE OF GLYCERINATED CALF LYMPH FOR PROTECTIVE VACCINATION AGAINST SMALL-POX.

THE terms of the Report of the Royal Commission on Vaccination, published towards the end of the year 1896, made it evident that there was a general feeling on the part of the Commissioners that the use of calf lymph should be encouraged as far as possible; and it was patent to those who grasped the full significance of the Report, that in order to fall in with popular sentiment, even apart from other considerations, some effort would be made by those in authority to examine carefully into the claims advanced on behalf of calf lymph vaccination as carried out at home and in European countries. For some time past it has been recognised by those who have been cognisant of Dr. Monckton Copeman's work on the "glycerination" of vaccine lymph, and especially of that derived from the calf, that the advantages connected with the use of this lymph are of such a nature that many of the objections that have been urged against the use of calf lymph are practically eliminated. Although this work has been going on in our midst, it appears that, in order to obtain any knowledge of the practical outcome of Dr. Copeman's investigations, we are compelled to turn our attention to the large vaccine establishments of France, Germany, Belgium and Switzerland, where, under State control, the use of glycerinated calf lymph has now come to be recognised as the method, of all others, which is attended with the greatest success.

The addition of a certain bulk of glycerine to vaccine material does not at first sight appear to be a very important matter, but, as Dr. Copeman has demonstrated, this glycerine does exert an extraordinary influence.

Taking the method employed in the Institute in Berlin as an example, we find that the vesical pulp collected from a single calf weighs from 10 to 15 grammes; to this is added a mixture of glycerine and water of equal parts, fourteen times the bulk of the vesicular pulp; it then, if used carefully, forms a sufficient volume to vaccinate 15,000 individuals.

All this we learn from the Report drawn up by the Medical Officer of the Local Government Board, in conjunction with Dr. Monckton Copeman, published in "The Supplement containing the Report of the Medical Officer for 1896–97 to the Twenty-sixth Annual Report to the Local Government Board."

The advantages early claimed by Dr. Copeman for this method are:

(1) That the addition of glycerine in this diluted form has the effect of ensuring the destruction of micro-organisms that are sometimes found even in the calf lymph collected under the very best conditions. It has been maintained that certain of the cases of erysipelas that have followed vaccination with calf lymph have been due to the accidental presence of certain of these organisms. Again, the possibility of infection with tubercle has sometimes been raised, though there is very little evidence of such infection being conveyed by vaccination; still the point has been raised, and it is right that it should be considered as a possibility. Glycerination of the lymph entirely does away with any danger from either of these or other allied sources. The addition of the glycerine kills off not only non-pathogenitic microbes, but such pathogenitic organisms as are ever likely to be found in vaccine lymph. This in itself, then, is a forward step of vital importance to those who, whilst fully convinced of the advantages of vaccination, and of the enormous preponderance of these over the possible disadvantages, are desirous that such disadvantages as there are shall be removed, and that every cause of objection should be done away with for those who have conscientious, even though unfounded scruples, against the use of lymph taken from the child, or from the calf under ordinary conditions.

(2) The dilution with glycerine appears to have absolutely no effect in diminishing the specific activity of the lymph, although it affects the bacterial flora of the lymph in such a marked degree. It is even maintained that such specific activity is actually increased, though it is difficult to see how this can be the case. It is possible, however, that various changes set up by bacteria are inhibited, and that in consequence the active elements in the lymph remain in a stable and unaltered condition for a longer period.

It is interesting to note in this connection that, although the lymph is diluted some fourteen or fifteen times, it remains sufficiently active at the end of three or four weeks to produce a good crop of vesicles when the same amount of the dilute fluid is used as is ordinarily employed of the undiluted vaccine. It is evident, therefore, that the amount of active principle present in ordinary vaccine is far in excess of what is necessary. That being the case the amount of available fluid is multiplied by fifteen, and to that extent the production of a good supply of trustworthy calf lymph is facilitated, and it becomes a comparatively easy matter to supply a pure lymph at a small cost. Hitherto at the animal vaccine establishment in Lamb's Conduit Street the amount that could be obtained from a single calf was, at the outside, only sufficient for the vaccination of some 200 to 400 patients, and this had to be done under somewhat unfavourable conditions—namely, directly from the calf to the arm of the patient—in order that there might be as few organisms in the lymph as possible, as naturally any organisms would multiply comparatively rapidly in stored lymph to which antiseptics could not be added. With the lymph from a single calf, used according to the new method, 4000, 6000, or even 15,000 vaccinations may be carried out, of course not at once from calf to arm, as the lymph may be kept under observation for some time, during which test-plate cultivations may be made, and the presence or absence of micro-organisms demonstrated. The glycerine does not kill certain organisms instantaneously. Consequently test-plates, made immediately after the emulsion has been prepared, may contain a number of organisms. In such a case the vaccine would be left to mature—*i.e.* to get rid of these organisms—which it will do in a few days at the outside. As soon as such organisms can no longer be demonstrated in plate cultures, or as soon as the exact period at which they disappear has been absolutely determined, the glycerinated vaccine may be used by the operator, who may have full confidence that no secondary or untoward conditions, which can in any way be attributed to impurity of the vaccine lymph, will arise.

In view of these facts, and of the splendid results that have been obtained in Paris, Brussels, Berlin, Cologne, Dresden and Geneva—the vaccine Institutes in which cities were specially visited and reported upon by Sir Richard Thorne Thorne and Dr. Monckton Copeman—and in view, also, of the recommendation of the Royal Commission on Vaccination, all who take an interest in this question (and the number of these is far greater than many people imagine) will hail with delight any measure brought forward by the Government to facilitate the preparation and encourage the use of glycerinated calf lymph, especially wherever it is found necessary to apply the compulsory clauses of the Vaccination Act, and also for vaccination generally.

Perhaps one of the main advantages adduced in favour of vaccination with calf lymph is that the animals may in the first instance be carefully selected, so that only such as are of sound constitution and good family history need be employed; but even then, under the old system, owing to the outlay involved if the calves were killed at once and not used for food, a post-mortem examination could not be obtained, or thorough inspection of the organs made. It was, therefore, not possible for the vaccinating officer to state that there was no disease in the animal. Now that such a large amount of lymph can be obtained from a single calf, it would scarcely be justifiable to neglect this post-mortem inspection; consequently, as the lymph should not be used for a few days after it has been taken and made into an emulsion, the medical officer is able to assure both himself and his clients, that the animal from which the special lymph he is using has been taken is absolutely free from flaw or blemish, whilst the after-treatment of the lymph with glycerine enables him to certify that the effects of accidental contamination from outside are completely neutralised.

It is somewhat humiliating to us as a practical nation to find that a method worked out theoretically by an Englishman should have received attention, and been applied practically in almost every important European country before it has been thought necessary to draw attention to it at home. Still, we are glad that at last Government has been brought to see its duty in this matter, and to make preparations for acting up to the light it has received.

For the information of our readers we may quote Sir Richard Thorne Thorne's conclusions, drawn up after visiting the establishments to which reference has already been made:—

"(1) It is desirable that vaccination, both primary and secondary, carried out under the auspices of the Government, should be performed exclusively with vaccine lymph direct from the calf.

"(2) There will probably be advantage in retaining, for a time at least, the system of calf-to-arm vaccination at the Board's Animal Vaccine Station for such parents and others as may specially desire it, and for the purposes of comparing its results with those following the use of calf lymph preserved in one or another way.

"(3) The distribution of calf vaccine from the National Vaccine Establishment should be limited to glycerinated or similar preparations of lymph and pulp material, in air-tight tubes, or other glass receptacles.

"(4) To give effect to the above it will be requisite that the Board's Animal Vaccine Station should be reorganised, both as regards construction and administration. Notably will it be requisite that it should include a properly equipped laboratory, under the direct supervision of a bacteriological expert."

It is to be hoped that in any legislative measure which may be formulated and passed, due effect will be given to each of these four conclusions, although from many points of view it would appear desirable that the second recommendation should be made to cover a comparatively short period, as most people who have studied the question are now fully of the opinion that calf-to-arm vaccination has no advantages over vaccination with glycerinated lymph, and few parents who are likely to express any opinion at all, may be expected to ask for calf-to-arm vaccination of their children.

We look upon this document as one of the most important that has been published from the Department for some time, and we heartily recommend a perusal of its contents to those who are in any way interested in the study of the vaccination question.

NOTES ON SOME VOLCANIC PHENOMENA IN ARMENIA.

As we descended from the central mountains of Armenia towards the south along the road from Akstafa to Erivan, we suddenly came upon a beautiful sheet of water lying glassy and restful in the lap of the mountains. Those on the left, sloped down to its shore with every diversity of valley, creek and headland, and with gently moulded outlines which told of subaerial waste, and gave the impression of a mountain land the base of which the waters had but recently begun to bathe. From the heights on which we stood the lake seemed to follow a somewhat narrow sinuous course, which suggested the idea that we were looking on a dammed-up valley. But it could not be the submerged end of a long valley invaded by the sea, for we were still between 6000 and 7000 feet above sea-level. On the right, beyond the lake, conical hills, often nicked at the summit, with long ridges radiating from them, rose in strong contrast to the more ancient rocks of the northern slopes, and suggested plainly by their geographical outline a volcanic region which had been so recently active that there had not yet been time for its distinctive features to have been obliterated.

Soon we wound our way round the north-western end of the lake, and found that we had to cross its principal outlet, and then immediately descend rapidly into the valley of the Araxes. Here, then, we might hope to see some reason for this strange holding up of such a vast body of water on the edge of the mountain land.

As we turned round to the right beyond the little village of Elenofka we found the passage barred by long moraine-like ridges. We had just seen snow-covered summits and glaciers in the Caucasus, a little further north, and moraines, telling of the former much greater extension of those glaciers. We asked ourselves whether similar conditions might not have produced glaciers and moraines here also on the slopes of the Armenian mountains? But when we reached the first of the ridges we found that it was not a moraine at all, but a lava-flow with scoriaceous surface and more solid rock within. The stream with its equalised flow had cut but a very small gap in these barriers, one after another of which had been thrown forward, and had built up a mass which, from the physical geography of the country, we inferred must be thousands of feet in thickness. What the depth of Lake Gokcha was we were not able to ascertain, but it runs for forty-three miles along the base of the mountains and widens out in places to a breadth of twenty miles. To save room our diagram (Fig. 1) is taken across the narrow western end, so that it does not indicate the proportion this enormous body of water bears to the size of the valley below. Should that lake by any great shock be suddenly let out—not an improbable catastrophe—what a terrible deluge would sweep the plain of the Araxes; and, if the lake were wholly or partly drained, what a history of the gradual heaping up of waters on the flanks of an active volcanic region might be studied in its depths.

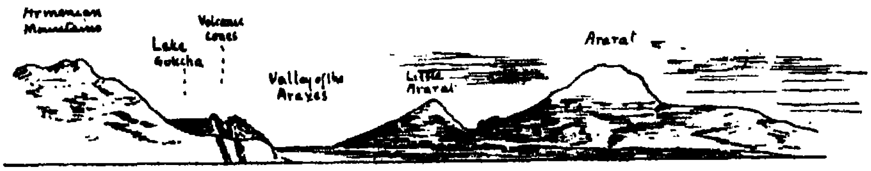


FIG. 1.—Diagram to explain the mode of occurrence and origin of Lake Gokcha.

Here we saw not a mountain valley dammed, but the whole foot of a mountain region enclosed by volcanic ejectamenta having their origin along a belt of country lying a little off and in front of the high ground. From this the inference is obvious that the outlet was not always where we crossed it, and we were therefore prepared to find here and there curious conditions of the rock pointing to a different line of exit for the percolating and overflowing water.

What struck us most in examining the outflowing stream at Elenofka was its very small volume considering the extent of the lake that feeds it, and we could see no evidence of any considerable difference of level between the late summer's flow and the winter's flood waters. The stream filled its channel up to its reedy green bank, and no bare beds of sand and gravel or heaps of torrent débris suggested that it ever rose any higher. Perhaps when the waters do rise, they find their way through broken or scoriaceous rock to other outlets.

Driving on through ridge and tumbled crag of brown and black cindery rock—the great barrier of lava that holds back the lake—we suddenly came to the southern flank. We looked out through an opening in the lava over the rich valley of the Araxes, and first caught sight of Ararat rising grandly alone into the soft southern sky. Distance did not dwarf its 17,000 feet; but whether it was active at the same time that the Elinofka volcanoes were locking up Lake Gokcha, I cannot say. Perpetual snow now covers this hill of ancient fires. There it has stood for ages, looking down on the region where tradition carries us back to the earliest homes of civilised man.

As we descended from the great masses of lava around Lake Gokcha, we suddenly came upon a most interesting and suggestive section, where the road winds under a cliff, partly natural and partly cut back for the road itself, so as to exhibit now a face of newly-bared rock. In this we saw alternations of dark green or brown-black obsidian, and a white product of decomposition of volcanic rock standing in vertical planes (see Fig. 2). The white rock is, especially in the upper part of the cliff, apt to be broken up into a kind of breccia made up of pieces of all sizes and shapes. The first impression produced by the section would be that it consisted of a number of bands of obsidian alternating with a coarse agglomerate of fragments of one and the same kind of decomposed igneous rock, and all turned on end by subsequent movement. But an examination of the ground soon showed that view to be untenable, because the section was cut through the terminal margin of a lava-flow which had come down from the great volcanic group forming the southern rim of Lake Gokcha (see Fig. 3, in which the arrow indicates the direction of flow). The obsidian bands are therefore at right angles to the bedding.

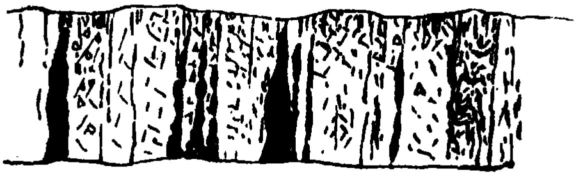

FIG. 2.

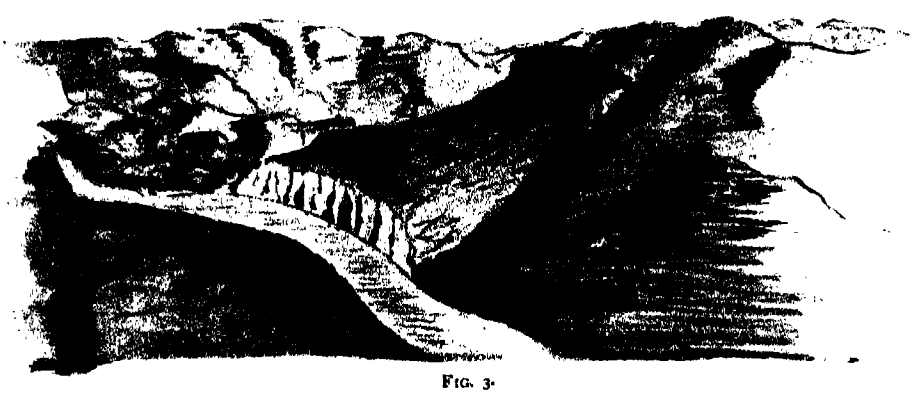

FIG. 3.

Another view was therefore suggested, namely, that the obsidian was injected or found its way along vertical fissures in the crushed and brecciated rock of an earlier flow. But had this been so, there seemed no reason to limit the injection to the vertical planes. The molten liquid mass would have penetrated in all directions through the fractured rock. Besides, an examination of the rock in detail showed that the obsidian was not injected, for it occurred in isolated masses in the midst of the white porcelanous or powdery rock. The plates assumed a fan-shaped arrangement in places, as if their position had been determined by joints converging downwards. The mode of occurrence of the rock suggested the true explanation of the phenomenon. The white rock was decomposed obsidian. The whole mass was a quickly cooled lava traversed by shrinkage joints at right angles to the cooling surfaces, and roughly parallel to the line of flow. Water followed the cracks, acted on the silicates, and changed the glassy lava to the white chalk-like mass in which bands of obsidian, preserved between the joints, still remained samples of what the whole rock once was.

A similar change may be observed at Obsidian Cliff in the Yellowstone Park in America, where the same alternation of bands of decomposed and sound obsidian may be seen as in the Armenian section, though not on such an extensive scale. The same process picks out by decomposition the spheroidal shells, which are invisible in the sound part. An analogous process may also be seen in the grand cañon of the Yellowstone River, where the rhyolites have been weathered into a white or yellowish, mealy-textured rock along the great fissure, which allowed a freer passage to, and still emits, in diminished quantities at the bottom of the gorge, heated water and steam from the dying-out volcanic furnace below.

So along the Armenian lava-flow water easily got in from the surface, or followed the longitudinal cracks in the rapidly cooled rock, and, being itself heated by the process, acted upon the silicates, and carried off the more soluble portions. A diminution in volume accompanied the process, and the reduced rock broke up.

May be the old valley down which this lava flowed was an ancient outfall of Lake Gokcha before its rim had been built up as high as it now stands. Perhaps at one time some of the water of the lake found its way through fissured masses to lower levels, and carried on the work of destruction within the rock itself.

We want many more facts respecting this most interesting district—we would like to know the depth of the lake, the direction of any observed lines of fissure, and if there is any evidence of the waters of the lake having ever been suddenly drained off into the valley of the Araxes. We hope, therefore, that Mr. Loewinson Lessing, whose knowledge and skilful arrangements enabled us to see so much of the district, and whose courtesy and thoughtfulness made our excursion so pleasant, may be able to carry on the work for which he is so well qualified, and will communicate to the world the result of his further investigations.

T. MCKENNY HUGHES.

PERIODIC ORBITS.

FOR some years past, Prof. G. H. Darwin has been engaged on the numerical solution of a particular case of the problem of three bodies, and at different times he has given some account of the progress he has made. He has now collected his very extensive material, relating to both the mathematical methods employed and the discussion of the numerical results, into one compact summary under the title of "Periodic Orbits," which appears in *Acta Mathematica*, vol. xxi. The special case treated by Prof. Darwin refers to one of three classes into which M. Poincaré has divided the periodic solutions of this problem. In this class, the motion is entirely in two dimensions, and the excentricity of the planet's orbit is very small; but Prof. Darwin further supposes the perturbed body to have infinitely small mass, and the planet's orbit to be absolutely circular. The discussion of even this one class has had to be restricted in the course of the work, on account of the heavy arithmetical labour which the method of tracing the orbits by mechanical quadratures involved. Retrograde orbits have not been considered, and the motion of superior planets is still engaging Prof. Darwin's attention. Some thirty examples of periodic orbits have, however, been examined; and though the author may speak of his results very modestly, there is no doubt but that his conclusions will be welcomed as a most interesting contribution to the study of celestial mechanics.

Prof. Darwin defines a periodic orbit as one in which a third body can continually revolve so as always to present the same character relative to the two other bodies of the system. These orbits are not necessarily confined to a single revolution round the primaries, or round any other point in space, but the difficulty of the determination of the path increases with the number of circuits described, and on that ground the present treatise is confined to the examination of "simple periodic orbits," or those which are re-entrant after a single circuit, though loops may, and do, occur in the orbit. In the system considered, the distance between the sun and the principal planet, here called Jove, is taken as unity, and the ratio of the mass of the sun to that of the planet as 10 : 1. This hypothesis differs considerably from the actual circumstances prevailing in our system, but it offers the advantage of exaggerating all the phenomena of perturbation, and permits the clear exhibition of the deductions in diagrams that are easily appreciated. Some of the stellar systems may offer conditions more nearly parallel to those here assumed. A looped orbit has been suggested in the case of one of the components of ζ Cancri, though possibly with insufficient data, and in some other cases, the presence of a disturbing body seems likely to produce an orbit of very irregular form.

We have accustomed ourselves to consider the relations of superior and inferior planets and of satellites to be fixed and definite, but Prof. Darwin traces the conditions under which these forms cease to be permanent, and when consequently the third body of a system can assume the characteristic motion of either an inferior planet or a satellite. With a particular value for the constant of relative energy, it is possible for both kinds of planetary and satellite motion to become confused, and for a body which originally started in one way to exhibit the peculiar motion of either of the other two. Prof. Darwin began his numerical work by an assumed case in which it was possible for an inferior planet and satellite to interchange their parts. The satellite was made to start at right angles to a line joining the sun and Jove, at a distance of 1·08 from the sun, Jove's distance being unity. The resulting orbit is fully drawn and shows how the body hangs in the balance, between the two centres, before the elliptic form of the orbit asserts itself, as the body approaches the sun. Starting the satellite from a conjunction remote from the sun, but at slightly different distances from Jove, it is found that the resulting orbits show a great diversity of character, which cannot always be foreseen. Perhaps the most remarkable curve in this family arises when the satellite starts at a point 1·095 from the sun. After making a loop, the satellite recrosses the line of conjunction and moves directly towards the planet, so that it is impossible to determine its subsequent path without very accurate computation. "I do not think," says Prof. Darwin, "any one could have conjectured how the body should have been projected so as to fall into Jove." The positions which give rise to periodic orbits are shown by the distances from the sun at which the curve meets the line of conjunction after one complete circuit. If for two selected points of projection, the curve returns to this line at places alternately nearer to and more remote from the sun than those from which it originally started, then there must be some point intermediate between these selected points at which the curve will be re-entrant. Other forms of orbits giving rise to distinct families, have been computed, and drawn, when the satellite is projected from points intermediate between the sun and Jove, and also from conjunction on the side remote from Jove. Most of these orbits do not possess the character of stability, a point which the author has considered with as much care as the form of the orbit itself. It has been questioned whether all orbits are not essentially unstable, if the number of revolutions be sufficiently great. The result of the present investigation is to show that orbits may be stable if the perturbation of Jove by the planet can be neglected. This is the only approximation that Prof. Darwin has permitted himself, and he remarks "that for a very small planet the instability must accordingly be a very slow process, and I cannot but believe that the whole history of a planetary system may be comprised in the interval required for the instability to render itself manifest."

WOLDEMAR VON SCHRÖDER.

HEIDELBERG has had to mourn the loss in rapid succession of three of its most distinguished professors—Victor Meyer, Erwin Rohde and, on January 28 of this year, Woldemar von Schröder.

Schröder was born at Dorpat in 1850, where his father was director of the Gymnasium. On his mother's side he inherited a taste for literature and poetry, but on entering the University at Dorpat, in 1868, he devoted himself to the natural sciences, possibly influenced thereto by his uncle, von Schrenk (of St. Petersburg), who was celebrated for his journeys and researches in Siberia. At first he studied chiefly chemistry and physics under Karl Schmidt and Arthur von Oettingen, and trained himself under Lemberg to that high pitch of analytical skill which he manifested in all his later work. After a break in his studies, due to persistent pains in the head and trouble with his eyes, he again returned to work; now, however, turning his attention rather into a biological direction. In 1878 he left Dorpat with the degree of Master of Chemistry, and went to Leipzig, where he was at once attracted by the striking originality and personality of Karl Ludwig, and in his laboratory saw for the first time the perfection of physiological experimenting. But Schröder was one of the few who were not content to learn by merely assisting Ludwig in personally carrying out all the experiments, and he struck out into paths of his own. Skilled as a chemist, he soon became an expert operator, and succeeded for the first time in successfully extirpating the kidney in birds, and thus settling a most important question as to the seat of formation of uric acid. In 1879 he became assistant to Schmiedeberg in Strassburg, and here it was that he carried out the great research with which his name will for all time be connected in the annals of physiology. Very little was at that time known as to the mode and seat of formation of urea, and Schröder threw a flood of light into the darkness. Having by extirpation of the kidneys, and artificial circulation through the excised organs, proved that urea is not formed by them, he next carried on an artificial circulation of blood containing ammonium carbonate through the muscles, and found that in them also no synthetic formation of urea takes place. He now turned to the liver and, again making use of artificial circulation, proved without any possibility of doubt the power of this organ to actively synthetise urea from ammonium carbonate and from certain substances present in the blood from an animal in full digestion. This was a great work, for not only did it reveal clearly a striking instance of synthetic activity in the animal organism, and thus place our belief in the fundamental similarity of plants and animal protoplasm on a firm basis, but it fixed definitely one seat of formation of urea in the animal body. In recognition of this work he received the degree of Doctor from the Natural Science Faculty of Tübingen in 1882, and similarly, and in the same year, he was made a Doctor at Strassburg, where he became Privat-docent in 1883. For this he wrote his inaugural dissertation on the alkaloids of opium, and thus diverged into that branch of science, pharmacology, which was henceforth to be the business of his life. During the next few years his chief works were on the physiological action of caffeine and of theobromine as related to caffeine, while at the same time he converted theobromine into a more soluble and assimilable compound, making it thus available for medicinal purposes. In 1890 Schröder was called to Heidelberg as Professor of Pharmacology, and he it was who really founded the existing Pharmacological Institute, turning the older accommodation to the best account, utilising or enlarging every corner of it, and completely remodelling and organising the teaching. Here he worked until his death, stimulating his pupils by his personal example and collaboration, brightening their labours by his sympathetic and genial ways, and impressing on all the right spirit of scientific life.

THE KEKULÉ MEMORIAL.

THE death of August Kekulé on February 13, 1897, terminated a career rich in scientific achievement. In him we have lost an investigator who has exerted a profound influence on the development of chemistry.

The theory of valency and of the linking of atoms, and our present views as to the structure of carbon compounds, have acquired their definite form and clearness by the labours of Kekulé. His theory of benzene derivatives, in particular, has given the most powerful impulse to investigation in the domain of pure chemistry; while no scientific theory has done more to promote the development of chemistry as a branch of industry. While Kekulé is eminent by his scientific achievements, he is not less so by reason of the effects produced by his teaching. The publication of his "Lehrbuch der Organischen Chemie" marked an epoch in the history of chemistry. This treatise has done more to familiarise chemists with modern views than any other work of the kind.

The greater number of German professors of chemistry, and many of those in other countries, have either studied under Kekulé or under those who were his pupils: and gratitude calls for the erection of some permanent memorial of his striking personality.

Such a memorial would be a statue in bronze of the founder of structural chemistry, which would be fitly placed in front of the Chemical Institute at Bonn—in the place where for thirty years he lived and taught and worked.

All friends, admirers and pupils of Kekulé are accordingly invited to contribute to this object. Subscriptions, which will be forwarded to the Central Committee at Bonn, will be received by Dr. Hugo Müller, 13 Park Square East, Regent's Park, N.W.

James Dewar.

Hugo Müller.
Francis R. Japp.
Raphael Meldola.

NOTES.

Acting under the rule which empowers the annual election by the Committee of nine persons "of distinguished eminence in science, literature, the arts, or for public services," the Committee have just elected Viscount Dillon (president of the Society of Antiquaries), Mr. R. T. Glazebrook, F.R.S., and Sir George Scott Robertson into the Club.

The meeting for the discussion of the scientific advantages of an Antarctic expedition takes place at the Royal Society this afternoon. We purpose giving a full account of the meeting in next week's Nature, accompanied by a map showing all known land south of latitude 45° S., with drift and pack ice limits, so far as known, and the positions and dates of the highest latitudes reached.

The Berlin correspondent of the *Standard* reports that the German Antarctic Expedition Committee, which met at Leipzig on Saturday last, unanimously resolved, after a long discussion, to advocate the despatch of a ship towards the South Pole on or near the meridian of the island of Kerguelen. Oceanic, geodetic, and biological researches are to be made during the voyage, and, if possible, the expedition will winter in the Antarctic zone. In that case geological observations are to be made at a fixed station, and exploring journeys on the inland ice and to the unknown west coast of Victoria Land, discovered by Sir James Clark Ross, will be undertaken in the spring. The return of the expedition, which will last two years in all, and will make observations on the home voyage as well as on the way out, will take place in the southern autumn. Dr. Erich von Drygalski, well known as an explorer of Greenland, was appointed the scientific head of the expedition.

LORD LISTER is suffering from a severe cold, and was prevented by it from occupying the chair at Dr. Nansen's lecture on Monday.

WE are glad to see the announcement that Sir Richard Quain's strength has so far improved that no further official bulletins will be issued.

THE Pasteur Institute at Paris has received a donation of 1600*l.* from Mme. E. Durand, for the purpose of carrying on investigations on tuberculosis.

THE personal estate of the late Mr. J. W. Zambra, formerly of the firm of Negretti and Zambra, the well-known philosophical instrument makers, has been valued at 176,075*l.*

THE fifth International Congress of Hydrology, Climatology, and Geology will be held at Liége this year, from September 25 to October 1, under the patronage of His Royal Highness Prince Albert of Belgium.

THE Physical Society of Frankfort-on-Main propose to erect a monument to Philipp Reis, the inventor of the telephone, and have appointed a committee to obtain subscriptions for this purpose. The estimated cost of the memorial is 1500*l.*

THE fourteenth International Horticultural Exhibition is to be held at Ghent from April 16 to April 24 next. This exhibition, which takes place every five years, is organised and managed by the Royal Society of Agriculture and Botany at Ghent It is under the patronage of the King and Queen of Belgium, and is subsidised by the national, provincial, and municipal Governments.

H.R.H. THE PRINCE OF WALES has consented to open the International Photographic Exhibition at the Crystal Palace on Monday, April 25, and not Wednesday, April 27, as originally announced. The latest date for the reception of exhibits in each section will therefore be two days earlier than that first stated on the prospectus.

AT the meeting of the Physical Society of London, to be held at Eton College on Saturday, February 26, the Rev. T. C. Porter will exhibit and describe several interesting experiments. The subjects with which he will deal are: (1) a new theory of geysers; (2) a new method of viewing Newton's rings; (3) experiments bearing on the sensation of light; (4) a method of viewing lantern projections in stereoscopic relief; (5) winter observations on the shadow of El Teide, with a new method for measuring approximately the diameter of the earth; (6) temperature of the water of Niagara.

THE death of M. Gauthier-Villars was referred to, with expressions of regret, at the meeting of the Paris Academy of Sciences on February 7. Since 1835 the *Comptes rendus* of the Academy have been printed by the firm of Gauthier-Villars, and, in spite of the large quantity of matter on a variety of subjects, and the idosyncrasies of authors, the hour of publication has never been delayed. The firm has published for many years the publications of the Bureau des Longitudes, those of the Paris Observatory, and of the Bureau Central météorologique. M. Gauthier-Villars also assisted the French Government and the Academy in the publication of the complete works of Lagrange, Fermat, Fourier and Cauchy, and his name is associated with many other scientific enterprises.

THE anniversary meeting of the Geological Society was held on Friday last. Mr. W. Whitaker, F.R.S., was elected president in succession to Dr. H. Hicks, F.R.S., whose presidential address appears in another part of the present issue. The new vice-presidents elected are Prof. J. W. Judd, C.B., F.R.S., and the Rev. H. H. Winwood. Prof. W. W. Watts has succeeded Mr. J. E. Marr, F.R.S., as secretary, the other secretary being Mr. R. S. Herries. To the list of members of Council were added the names of Dr. G. J. Hinde, F.R.S., Mr. W. H. Hudleston, F.R.S., Prof. H. G. Seeley, F.R.S., Prof. W. J. Sollas, F.R.S., and Mr. A. S. Woodward. The medals and prize-funds were awarded to the geologists whose names have already been announced (p. 252).

SURGEON-MAJOR BLACK, Edinburgh, has received a letter from Mr. C. L. Wragge, dated Sydney, January 7, referring to a new high-level meteorological station. In the course of the letter Mr. Wragge says:—"You will be pleased to know that I have quite successfully established a mountain experimental observatory on the summit of Mount Kosciusko 7328 feet above sea-level, and the highest point in all Australia; also a sea-level station on the south-east coast adjacent at Merimbula, where simultaneous observations are taken. The hours are midnight, 4 a.m. and 8 a.m.; noon, 4 p.m. and 8 p.m.; also half-hourly from 8.30 a.m. to 11.30 a.m. inclusive. Simultaneous readings are also taken at a new station in Sydney, at Sale in Victoria, and at Hobart, and on Mount Wellington, Tasmania."

THE meeting, held in the rooms of the Manchester Literary and Philosophical Society on February 16, to consider what should be done to assist in making the forthcoming Congress of Zoology a success, was well attended by representatives of various natural history and scientific societies in the centre and north of England. Mr. J. Cosmo Melvill presided. Prof. S. J. Hickson explained to the meeting the objects of the International Congress of Zoology and the probable programme of the week in August at Cambridge. The following resolution was then proposed by Mr. Masefield, president of the Conchological Society, and carried unanimously:—"That this meeting of persons resident in the centre and north of England, and interested in zoological progress, offers its most cordial support to the Committee now organising the fourth meeting of the International Congress of Zoology, to be held in Cambridge in the last week of August, and expresses a sincere hope that all societies instituted for the study of zoology and kindred subjects will contribute in accordance with their means to the funds of the Congress, and appoint one or more representatives from their members to attend the Congress." The delegates at the meeting were enthusiastic about the Congress, and their cordial co-operation will encourage as well as assist directly the work of the Executive Committee.

AT its annual meeting on February 2, the Russian Geographical Society awarded a special Constantine medal to Dr. Nansen; a Constantine medal to V. I. Roborovsky, for his journeys in Central Asia; the Count Lütke's medal to I. I. Strelbitzky, for his journeys in Persia and Manchuria in 1891–96; the new Semenoff's medal to Dr. Sven Hedin, for his three years' journeys in Central Asia. A large gold medal of the Society was awarded to I. K. Zhdanoff, for his ethnographical works, and especially for his work on "Russian Epical Poetry"; and small gold medals to Th. Witram, for pendulum measurements in the Far East; to F. Sperck, for his large work on the climate of the Astrakhan region; to S. Rybakoff, for the collection of specimens of musical texts of songs amongst the Ural natives; and to S. Gulishambaroff, for his work "The World's Trade in the Nineteenth Century and Russia's Part in it." Silver medals were awarded to MM. Pastukhoff, for his ascension of the Elbrus; Abels, for hypsometrical measurements in the Urals;

B. A. Fedchenko, for a communication on the Talas Alatau; Timonoff, for a paper on the water-communications on the tributaries of the Amur; Sapozhnikoff, for work on the glaciers of the Altai; Kovanko and Semkovskiy, for the organisation of international balloon ascensions in which the Society took a part; and to Prince Obolensky, Tomilovskiy and Utyesheff, for their daily observations upon the motion of the clouds.

MR. LEONHARD STEJNEGER, of the U.S. National Museum, paid another visit to the Russian Fur-seal Islands (Commander Islands) in the Northern Pacific, last year, by order of the U.S. Government, and has just issued his report (Treasury Department, Document No. 1997). The examination of the "Rookeries" was made mostly in company with one of the British Commissioners, Mr. Barrett-Hamilton, and appears to have been a work of some difficulty and danger, owing to the wild weather generally prevalent, and the utter absence of means of communication. Mr. Stejneger's general conclusions demonstrate "a very great decrease in the breeding females" of the Fur-seals since 1895, when he made his last official report (U.S. Fish-Commission, *Bulletin* for 1896, Article 1). He also alleges "great mortality in the pups, due to starvation." He comes finally to the conclusion that a *sapuska*, or total prohibition of killing seals on land for a period of years (which he formerly advocated), would be rather an injury than a help to the seal-herds, as it would "increase the number of superfluous bulls."

SINCE he succeeded Sir Harry Johnston as Commissioner and Consul-General of Nyasaland, Mr. Alfred Sharpe has not ceased in the good work carried on so long by his former chief, of collecting and sending home examples of the fauna and flora of that Protectorate. Mr. Sharpe is now on his way home on leave, much impaired in health, we regret to say, from his long stay in the tropics, but brings more collections with him. A memoir, by Mr. Thomas, on the mammals procured by Mr. Sharpe, will appear in the next part of the Zoological Society's *Proceedings*, and Captain Shelley is at work on the birds obtained by this energetic administrator.

THE colonial report on "Cocos-keeling and Christmas Islands," 1897 (c.-8650-14) contains a few useful natural history and other notes. A small brilliant red crab is frequently seen up the hills, running in and out of holes or from under stones. Once a year, in the month of December or January, the male and female travel down to the sea margin, where the female deposits her eggs, and the parents again return. They take fifteen days going and fifteen days returning, and travel in bodies like ants. After the eggs are hatched, the young, when big enough, move up the hill. Darwin doubted whether the crab climbed trees; but it is now a well-ascertained fact, though the purpose is still unknown. Both Mr. Forbes and the reports of H.M.S. *Challenger* describe the white tern or noddy as a beautiful bird with black eyes; but no mention is made of the beautiful purple-blue of the beak up to the nostril, the feet and the tarsus. This is probably due to the fact that two or three hours after the birds are shot the colour of the beak and feet die away. A short description of three native dances is also given.

PROF. J. C. EWART, F.R.S., contributes to the *Zoologist* an illustrated article upon zebra-horse hybrids. His experiments prove that it is a comparatively simple matter to cross various breeds of mares with a Burchell Zebra, and, if experts are to be trusted, the hybrids promise to be as useful and hardy as they are shapely and attractive. The preliminary difficulties having been overcome, Prof. Ewart points out that it remains for those in authority to take such steps as may be necessary to ascertain of what special use, if any, zebra hybrids may be in the various parts of the Empire, but more especially in Africa and India.

A SNOWSTORM of considerable severity occurred over the south-western districts of England during Monday night, the snow gathering to a considerable depth in places, and causing much inconvenience and delay to ordinary traffic. In parts of Devon, Somerset and Dorset, the drifts were several feet deep. At Hurst Castle, Hants, a reporting station of the Meteorological Office, the melted snow and sleet measured 1·6 inches of water. Thunder and lightning were also experienced during the storm. This disturbed weather was occasioned by the arrival of a shallow cyclonic area over the south-western portion of our islands, which lingered in those parts during Monday and Tuesday.

THE U.S. *Monthly Weather Review* for November last contains an account of the celebration of the fiftieth anniversary of the establishment of the Royal Meteorological Institute in Berlin, on October 16, 1897. The jubilee festivities were divided into three parts: an address in the Memorial Hall of the Royal Geodetic Institute, an inspection of the magnetic and meteorological observatories of the Institute, and a banquet. The high recognition given in Germany to meteorological science was evidenced by the presence of the Emperor and Empress, who were accompanied by a brilliant retinue, and listened to the address of Dr. v. Bezold, the Director, who sketched the activity of the institution during the whole period of its existence. At the present time the organisation consists of 188 stations for regular observations, 1336 thunderstorm stations, and 1844 rainfall stations. Various experimental investigations are conducted at the Potsdam Observatory, and, owing to the generosity of the Emperor, scientific balloon ascents on a large scale are occasionally made for the study of the physics of the upper air. At the close of the address, the Minister of Education announced certain decorations to be given in connection with the celebration. The great gold medal in science was presented to Dr. v. Bezold, and Orders of the Crown or of the Red Eagle were presented to Dr. Hellmann, Dr. Sprung, Dr. Vogel, and to Herr Treitschke, proprietor of the observatory on the Inselsberg, near Erfurt, and to various other scientific men. Numerous addresses and telegrams of congratulation were received from all parts, including one from the Grand Duke Constantine, on the part of the Imperial Russian Academy of Sciences.

IN his "Twelfth and Concluding Memoir on the Theory of Screws," published in the *Transactions of the Royal Irish Academy*, Sir Robert Ball completes the solution of a problem which has for the past five-and-twenty years been associated with his name. A feature of his paper is the series of summaries of this and the eleven preceding memoirs, and we feel that we can do no better than quote in his own words Sir Robert Ball's summary of his latest investigation: "At last I succeeded in accomplishing what I had attempted from the first. I could not develop the complete theory, which I felt certain must exist, until I had obtained a geometrical method for finding the instantaneous screw from the impulsive screw. When this was accomplished in the midsummer of 1897, the geometrical theory in Dynamics, which I had striven for a quarter of a century to obtain, was at last manifest. How my difficulties were overcome has been set forth in this Memoir. There are, no doubt, many other questions that would repay investigation at almost every stage of the subject. But the problem which I had proposed to myself so many years ago, and which I have steadily kept in view ever since, having been at last resolved, I have felt that this series of papers should cease."

MR. E. CHARLES HORRELL, writing in the *Journal of Botany* for February, invites the co-operation of bryologists in working out the comital distribution of British mosses in the way that the distribution of flowering plants was done by Watson. With the object of seeing how far the lists of mosses already published would enable him to compile a census of the 112 Watsonian vice-counties, the writer has looked through most of the magazines, county floras, proceedings of local natural history societies, the Botanical Record Club's Reports, &c., in the library of the British Museum, and he finds that fairly good lists have been published for about fifty vice-counties; there are, therefore, about sixty-two vice-counties in Great Britain for which he can find no lists of the commoner mosses. Mr. Horrell has already received lists or offers of assistance from correspondents in about thirty-four vice-counties, but would much like to find a moss student in each vice-county who would undertake to prepare a list of his district during the next two or three years. Mr. H. N. Dixon and Mr. E. M. Holmes have offered their aid in examining doubtful or critical species. Mr. Horrell's address is 44 Brompton Square, London, S.W.

In a contribution to the *Transactions* of the Nova Scotia Institute of Science, ix., Mr. E. H. Archibald describes a series of determinations, made at Dalhousie College, of the conductivity of aqueous solutions containing potassium and sodium sulphates. The object was to ascertain if the conductivity was calculable in the case of mixtures of these solutions from the formulæ given by the dissociation theory of Arrhenius and others. It would appear that for mixtures of solutions of these salts, not more concentrated than 0·8 equivalent gramme-molecules per litre, it is possible by the aid of the dissociation theory to compute the conductivity within, or but little beyond, the limits of the error of observation. For more concentrated solutions the differences between the calculated and observed conductivities ranged up to 1·47 per cent.; but this discrepancy seems attributable, in part at least, to certain asssumptions regarding the ionisation-coefficients, which could not be regarded as rigorously correct, except at infinite dilution.

Messrs. Macmillan and Co. will publish in a few days the first volume of a comprehensive treatise on "Magnetism and Electricity," by Prof. Andrew Gray, F.R.S. In this work an attempt has been made to present the subject from the beginning from the point of view of action in a medium, and to bring the experimental and theoretical results described as far as possible down to date. The present volume, though it takes for granted a knowledge of some of the most elementary phenomena and apparatus, aims at giving an account of experimental work as well as of the related magnetic or electric theory. It includes the ordinary phenomena of magnetism and their theory, a discussion of electrostatics and of steady flow of electricity, of electromagnetism and of the electromagnetic theory of light. The treatment is as far as possible dynamical, and to facilitate reference to dynamical theorems, a chapter on general dynamics has been included in this first volume. In Volume ii. will be given, among other matters, an account of experimental work on magnetism, of recent work on Hertzian, Röntgen, and other radiations, and of general dynamical theories of electromagnetic action, a continuation of the discussion of the voltaic cell begun in Volume i., and a chapter on electrolysis.

The Mexican Scientific Society, which is called "Antonio Alzate," is doing excellent work, to judge from the recent numbers of its *Memorias* which have reached us. Among other papers we find seismic observations at Orizaba, by M. C. Mottl; physico-chemical studies on the fat of the Yoyote shrub (*Thevetia yecotli*), by Prof. Villaseñor; on the decimalisation of the circle and of time, by M. J. de Mendizábal-Tamborrel; on the concentration of auriferous and argentiferous minerals, by T. L. Laguerenne; on the augmentation of weight of tuberculous and anæmic patients in rarefied air, by Dr. D. Vergara Lope; studies on the transpiration of Mexican plants, by Prof. L. G. Seurat; on the syrup of iodide of iron, by Prof. F. Solórzano; on orogenic movements, by M. P. C. Sánchez; on the temperature of plants, by MM. Moreno and Anda; measurement of the tension of the blood of the dog, by Dr. D. Vergara Lope; and formulæ for the velocities and pressures in guns, by M. F. Angeles; as well as reviews of books, &c. The Society, besides publishing these *Memorias* in a convenient size for binding up with the majority of octavo scientific papers, has adopted the excellent plan of beginning each paper on a right-hand page; any specialist can thus bind up separate papers on selected subjects without impairing the rest.

A recent number of the *Cape of Good Hope Agricultural Journal* contains an article on "The serum method of treating cattle as a preventive of rinderpest in South Africa," in which the joint report of the French experts and the Government Veterinarian is given *in extenso*. It contains rules for the application of the method of treating cattle by the injection of protecting blood, and attention is called to the importance of procuring the blood from animals which have suffered from rinderpest in its most severe form, and which have been "salted" or rendered immune to the disease one to five months previously, and have received at least one injection of rinderpest blood. It is urged that general measures should be taken throughout the whole of South Africa to prevent the spread of rinderpest, the protective measures already adopted by the Governments of the South African Republic, Orange Free State, and the Cape Colony have had some good effect, but it is feared that unless further and more vigorous steps are taken, the epidemic will conquer the whole of South Africa. If we consider that it was in the beginning of the year 1896 that rinderpest first made its appearance in Matabeleland and Mashonaland, and in less than eighteen months had destroyed all the cattle of these two countries, and had also overwhelmed the territory of the South African Republic and the Orange Free State, the necessity for united and strong action appears sufficiently imperative. It is at present, the report tells us, spreading from north to south, and from east to west, and seriously threatens the herds of the Cape Colony, Basutoland, Natal, and Zululand. As regards the subsequent use of the carcases of rinderpest animals, the consensus of opinion appears to deprecate] as unsafe the practice of simply salting and drying rinderpest oxen hides, whilst it is also stated that the farmer cannot be trusted to convert fat into soap without risk of accidentally spreading the disease.

The Kekulé Memorial Lecture, delivered before the Chemical Society on December 15 (see p. 180), by Prof. F. R. Japp, F.R.S., is published, with a portrait of Kekulé, in the February issue of the Society's *Journal*.

Under the title]of "A Visit to Giessen; or, Thoughts on Liebig and Chemistry in Germany," Prof. Senier, of Queen's College, Galway, recently delivered a lecture. The lecture has now been published by Mr. Edward Ponsonby, Dublin, and it makes a very interesting pamphlet on Liebig and his work.

The second part (for February 1898) of the monthly *Journal of Applied Microscopy*, published by the Bausch and Lomb Optical Company, Rochester, N.Y., contains a full account, with illustrations, of the very extensive and complete laboratories connected with Cornell University, viz. those for botany, microscopy, histology, embryology, bacteriology, and pathology.

Three well-arranged catalogues of works on various branches of the mathematical and physical sciences have just been issued by Messrs. William Wesley and Son. The catalogues include works from the libraries of the Rev. A. Freeman, Dr. Albert Marth, and Dr. Hind. Rare and valuable memoirs and books are enumerated in the lists, and the scientific bibliophile who consults the catalogues will be repaid for his trouble.

The results of meteorological observations made at Bangalore, Mysore, Hassan, and Chitaldrug, under the direction of Mr. J.

Cook, during 1896, has just been issued from the Mysore Government Central Press. In addition to meteorological statistics, the volume contains several plates, upon which the observations are represented graphically. The Report of the Meteorological Service of Canada for the year 1890 was also received a few days ago, together with a report on the observations made during 1895. Both of these reports are almost completely taken up with rows of figures referring to the meteorology of the Dominion.

THE Manchester Museum, Owens College, has just published, as a museum handbook, Parts ii. and iii. of a Catalogue of the Hadfield Collection of Shells from the Loyalty Islands. Since the first part of the catalogue was published, further consignments of shells have been received at the museum, the number of species recorded being thus increased from 630 to 860. The complete catalogue should be of considerable value to conchologists, as the collection of shells described in it is the largest and most important that has been received in this country from the Loyalty Islands.

THE first number of the thirty-second volume of the *American Naturalist* marks the issue of the magazine in a new and more attractive form. It is the purpose of the editors to make the periodical a means of encouraging the movement towards a closer union of the natural sciences. Superficial observations and poorly-grounded speculations are not to be published in its pages, but only articles and other contributions which have significance from various points of view. This ideal is a commendable one, and it remains for American naturalists to help the journal to attain it.

THE current number of the *Journal of the Royal Microscopical Society* (published bi-monthly on the third Wednesday in February, April, June, August, October and December) contains the tenth and concluding part of Mr. F. Chapman's very important account of the Foraminifera of the Gault of Folkstone. The greater part of the number is, as usual, occupied by the summary of recent researches in zoology, botany, and microscopy (structural and applied). The object aimed at is to give a brief abstract of every important paper (not purely systematic) in these departments of science, each section being under the care of a specialist sub-editor. The paragraphs on bacteriology are especially full and complete.

UNDER the title of the "Universal Lamp Time Chart," Mr. D. E. Benson, of Southport, is publishing an accurate and ingenious chart, constructed by Mr. G. Napier Clarke and himself, to show graphically the time at which cyclists must light up on any day of the month in any part of the British Isles. Separate charts are required for each month, and also for England and Wales, Scotland and Ireland; but though this will probably prevent the charts from being widely used, the idea of representing by a graphic construction the times for lighting and extinguishing lamps in different latitudes and longitudes in the British Isles is so good, that the authors deserve encouragement. Another publication in which those of our readers who ride cycles will be interested is "The Cyclist's Pocket Book" (Archibald Constable and Co.). The book contains a large amount of useful information and memoranda on the practice of cycling, and a few hints on the initial treatment of the commoner casualities to which cyclists are liable.

THE additions to the Zoological Society's Gardens during the past week include two Australian Sheldrakes (*Tadorna tadornoides*) from Australia, two Chinese Quails (*Coturnix chinensis*) from China, six Pintail (*Dafila acuta*), European, purchased; a Great Kangaroo (*Macropus giganteus*), an Australian Cassowary (*Casuarius australis*) from Australia, deposited.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN MARCH 1898:—

March 1. 8h. 49m. Jupiter's Sat. IV. in conjunction S. of planet.
2. 10h. 10m. to 12h. 33m. Jupiter's Sat. III. in transit.
2. 10h. 51m. to 12h. 33m. Jupiter with only one visible satellite.
2. 13h. 40m. to 14h. 36m. B.A.C. 2238 (mag. 6·5) occulted by the moon.
4. 7h. 10m. to 8h. 29m. d^1 Cancri (mag. 5·9) occulted by the moon.
4. 8h. 44m. Minimum of β Persei (Algol).
9. 11h. 12m. to 11h. 51m. *q* Virginis (mag. 5·7) occulted by the moon.
9. 13h. 29m. to 15h. 14m. Jupiter with only one visible satellite.
9. 13h. 29m. to 15h. 53m. Jupiter's Sat. III. in transit.
9. 14h. 12m. Jupiter's Sat. IV. in conjunction N. of planet.
13. 14h. 38m, to 15h 49m. α Scorpii (Antares, mag. 1·1) occulted by the moon.
15. Illuminated portion of disc of Venus = 0·993.
,, ,, ,, Mars = 0·968.
16. 16h. 46m. Jupiter's Sat. III. begins transit.
16. 16h. 46m. to 16h. 58m. Jupiter with only one visible satellite.
20. Pons-Winnecke's comet due at perihelion.
21. Minor axis of Saturn's outer ring 17″·63.
24. 10h. 27m. Minimum of β Persei (Algol).
25. 12h. Jupiter in opposition to the sun.
Equatorial diameter = 44″·95.
Polar ,, = 42″·13.
26. 2h. Mercury in conjunction with Venus. Mercury 1° 14′ N.
26. 9h. 24m. Near approach of 23 Tauri (mag. 4·2) to the moon.
27. 7h. 16m. Minimum of β Persei (Algol).
30. 11h. 13m. to 12h. 14m. δ Geminorum (mag. 3·7) occulted by the moon.

ANOTHER LUNAR HOAX?—From very early times the moon has frequently been selected as a suitable object upon which to exercise the imagination or base an elaborate hoax. We may remember that Hubert gravely declared to King John "that five moons were seen to-night: four fixed: and the fifth did whirl about the other four, in wondrous motion." Such rough descriptions were good enough for the times in which they were uttered; but in days of more exact knowledge, the lunar fable must be prepared with greater elaboration and decked in a more scientific garb. When this century was young, a tale obtained some credence, because it was artistically disguised, concerning what astronomers could see on the moon's surface. It was reported that Sir David Brewster and Sir John Herschel had seen a lunar forest with trees resembling "the yews grown in English churchyards," and a "lunar ocean breaking in large white billows upon the strand, while the action of very high tides was quite manifest upon the face of the cliffs for more than a hundred miles." Now, at the end of the century, comes the latest lunar myth, and it necessarily must be surrounded with still greater nicety of detail, and clothed with an accurate terminology.

The author of the alleged discovery in this instance is Dr. Georg Waltemath, an astronomer of Hamburg, and his assertion is, that there is evidence of the existence of a second moon, circling about the earth, but with such low reflective power that it has usually escaped observation even when in opposition. The author has perceived the desirability of making this hypothetical moon do a useful work in celestial mechanics, by explaining that the difference between the observed and computed secular acceleration of the moon's mean motion arises from the action of the newly discovered body. Perhaps it might also, with a little art, be made to explain the motion of the perihelion of Mercury. A new comer who is able to remove some existing difficulties, is naturally more welcome than one who might introduce fresh disturbances. Therefore the mass must not be very great, and Dr. Waltemath assigns to the new body that he has discovered or deduced, a mass of 1/80 of that of the moon, and a diameter of 700 kilometres. The distance is put at rather more than one million kilometres, 2·67 times the distance of the moon, and this gives the sidereal period 119·207434 days. The mean daily motion is given to the ninth decimal of a degree. We cannot say here what is sometimes said of a long row of decimals: the more figures one gives, the greater the chance for some of them being correct. The anomalistic period, too, is given with sufficient accuracy; so is the excentricity and the longitude of the node; everything, in fact, to enable an astronomer to compute the position of our new satellite. It is, of course, quite possible that Dr. Waltemath fully believes in the existence of this object. In that case we should say, he is the only person who does; for when we ask on what kind of observation does this very accurate orbit rest, we find that the author has employed that large collection either in which persons have believed that they have seen objects of doubted value transiting the sun, whether bright or dark. He seems to have trusted to those wild and reckless assertions that are made from time to time about "ruddy fireballs" or "night suns," or other vague descriptions, and on such loose and inaccurate data he has unfolded his strange and wondrous tale. This hypothetical satellite ought to have been seen transiting the sun on February 3, and, if we have correctly apprehended the author, may even yet be seen on July 30.

OCCULTATION OF CERES.—The extremely rare phenomenon of the occultation of Ceres, on November 13 last, has been observed by M. Schorr, of Hamburg, and M. Harzer, of Kiel. A note in the *Bulletin de la Société Astronomique* for February states that only the reappearance was possible to be observed, and it was noted that the increase of light during one or two seconds was gradual, and not sudden as in the case of a star.

A REMARKABLE OBJECT.—In Circular No. 46 from the Wolsingham Observatory, dated February 16, the Rev. T. E. Espin states that "a remarkable object hitherto unrecorded was discovered on January 16, and seen on three other nights. It is elliptical, one degree long, major axis 336°, and rather resembles some obscuring medium than a nebula, and is, I believe, unique." This object is situated on the northern border of Perseus adjoining the constellation of Auriga, its position being:

R.A. 4h. 26m. 0s., Decl. + 50° 44′ (1855).

VARIABLES IN STAR CLUSTERS.—Prof. Pickering, in Circular No. 24 from the Harvard College Observatory, states that "since the announcement made in Circular Nos. 2 and 18, of variables discovered in clusters, a further examination of the clusters ω Centauri, Messier 3, Messier 5, and N.G.C. 7078 has been made by Prof. Bailey. As a result, the numbers of known variables in these clusters have been increased by 62, 19, 22 and 24, respectively, making the total numbers 122, 132, 85 and 51, or 390 in all four clusters. Adding to these the 47 already announced in other clusters, makes the total number 437."

In the *Bulletin de la Société Astronomique*, M. A. Chévremont announces the discovery of a variable star upon the eastern margin of the globular cluster in Aquarius (M. 2). Whilst the stars of the cluster are of about the 15th magnitude, this new variable rises to mag. 12, at maximum, and is probably distinct from the cluster itself. It has a period of about thirty days, gradually decreasing from maximum to its minimum of mag. 14, in about fifteen days; the actual form of the light-curve is, however, only vaguely known, other observations being required to replace the hiatus of its ascent.

A LARGE REFLECTING TELESCOPE.—We learn from *Popular Science News* that another great telescope is approaching completion. In 1895 the Rev. John Peate commenced at Greenvill, Pennsylvania, the construction of a mammoth glass speculum for a reflecting telescope designed for the American University, Washington. After two years of arduous toil, Dr. Peate has given the great mirror its final touches—that is, in grinding and polishing—and it is now ready for silvering and for the further and important stage of mounting. This large disc of glass is more than 61 inches in diameter.

PARALLAXES OF STARS.—From observations made at the Cape Observatory, Dr. Gill concludes that the parallax of α Centauri certainly lies between the limits 0″·74 and 0″·75. This is equivalent to a distance of 275,000 times the radius of the earth's orbit. In the same journal (*Bulletin de la Société Astronomique*), we are informed that Dr. Gill comes to the conclusion that the parallax of Rigel is not greater than 0″·01, hence the distance of this star is certainly more than 20 million times the distance of the sun; it has, therefore, a "light journey" of 320 years.

The same author, in the *Monthly Notices* for January, gives, from his most recent researches, the parallax of α Gruis as 0″·015 ± 0″·007.

From measures of the mean parallaxes of the stars β, γ, δ, ε and ζ in Ursa Major, M. Hoffler has obtained the small value of 0″·0165 ± 0″·011. This number indicates that the system formed by these stars is separated from the earth by such a distance that it would take 200 years for the light to reach us. The distance of β and ζ is at least 4 million times greater than that which separates the earth from the sun. From the calculations made by this astronomer, ε Ursæ Majoris would be a star forty times brighter than Sirius, which, at the present distances of the stars, is considered the most brilliant in the sky.

FURTHER EXPLORATIONS IN AMERICAN MOUNDS.[1]

THE greater part of this volume is occupied by Mr. Moore's account of his systematic exploration of the mounds on the Georgia coast, the Marquis de Nadaillac's short paper being added to draw attention to the parallelism between burial customs on both sides of the Atlantic. Mr. Moore's contribution is a worthy continuation of his previous work, and the classified results of his numerous excavations, accompanied by excellent diagrams and illustrative plates, form a welcome addition to the material already existing for purposes of comparative study. Americans have every reason to be satisfied with the manner in which the archæological investigation of their country is being carried out: such researches as these of Mr. Moore in Georgia, and those of Mr. Cushing among the Keys of Florida, reflect the greatest credit upon all who have contributed to bring them to a successful issue.

The general results of these explorations tend to confirm in a striking degree the conclusion that men in similar states of primitive culture hold similar views upon all the fundamental questions of life and death. Such resemblances are not merely confined to generalities; they may be observed in the most minute matters of detail. Thus not only does the puzzling coexistence of inhumation and incineration recur as frequently in American as in European barrows, but many peculiarities of interment, noticed by Canon Greenwell and others, are repeated in a very remarkable manner in these Georgian mounds. Amongst these peculiarities may be instanced the preference shown for the southern and eastern sides of mounds; the laying of unburned skeletons upon one side and in a contracted position; the presence of charcoal, and pigments like powdered hæmatite; the deposit of potsherds belonging to *different* broken vessels, and the protection of bodies by coverings of wood. But in spite of these numerous coincidences we are as far off as ever from discovering the psychological laws which regulated the disposal of the dead by primitive man. Mr. Moore found bodies in all kinds of positions. They were "flexed" upon one side, or extended at full length, sometimes in anatomical order, sometimes showing signs of having been transferred to the place of burial after the flesh had been removed by exposure to the air; bones of one or more skeletons were "bunched" in heaps; confused masses of bones belonging to many different persons occurred together, some being calcined, others not; there were "pockets" of cinerated remains; urn burials, both cremated and uncremated; and unburned bodies placed upon the sites of fires. In a word, the apparent confusion reaches an extreme degree, and almost the only regularities of association which Mr. Moore ventures to point out are the more frequent presence of implements and ornaments in the neighbourhood of confused masses of bones, their comparative scarcity with flexed burials, and their complete absence in the neighbourhood of extended skeletons, though these last were generally at the base of the mound, and were often placed in large artificial excavations. As to the general question of the simultaneous occurrence of inhumation and cremation, we must still, perhaps, fall back on the former hypothesis that mere juxtaposition with fire as a ceremonial purification may have been in some cases considered equally efficacious with the actual incineration of the bones. The Marquis de Nadaillac has brought together, with admirable clearness and brevity, a mass of negative evidence proving that no distinctive significance can be proved to attach to either of the two great methods of burial; indeed, in places like Hallstadt the confusion seems absolute.

---

[1] *Journal of the Academy of Natural Sciences of Philadelphia*, 2nd series, vol. xi. Part 1, Philadelphia, 1897. (1) "Certain Aboriginal Mounds of the Georgia Coast," by Clarence B. Moore. (2) "Inhumation and Incineration in Europe," by the Marquis de Nadaillac.

The people who built these mounds must have been a race with very little stone, and almost without copper. Of this metal only a chisel and a few ornaments were found, among the latter being a ring still in its place upon a finger-joint. Their pottery was well represented, though lacking in diversity of type. It was ornamented by cord-marking, by incised and painted designs, and by complicated stamped patterns, some of which give the impression of having been derived from the grain of wooden ware, while others appear to owe their origin to life forms. All the types discovered are copiously illustrated in the plates at the end of the book, and in the woodcuts inserted in the text. The tobacco-pipes discovered differed from those found in Florida, and a mortuary earthenware with a ready-made perforation at the base was non-existent.

Of the other objects found associated with bodies, those made of shell were the most numerous. They included various implements, some possibly agricultural, drinking cups, ornamented gorgets, and large numbers of beads, the latter hardly ever showing traces of contact with fire. Objects of stone and chert were less numerous, but among them may be mentioned celts, hammers, lance and arrow heads, and discoidal stones smaller than those used in the game of *Chungke*, but probably employed in a game of a similar kind. The small pebbles, frequently found in little heaps near human remains, are supposed by Mr. Moore to be the contents of rattles, the turtle-shell covering of which has decayed away. Bone pins were of frequent occurrence; and animals' jaws ground away on the lower part, leaving a flat surface, were discovered in a few instances. Almost everything made of wood had entirely disappeared. What the art in wood of the mound-builders may have been we must conjecture from the discoveries made in the Florida Key dwellings, where the peat has been instrumental in arresting decomposition.

The south-eastern corner of the United States is an area of peculiar ethnographical interest, owing to its proximity to the greater Antilles and to South America: it is fortunate that its exploration has been entrusted to such competent hands, and that the results are published in so admirable a manner.

A JUBILEE VOLUME OF "WIEDEMANN'S ANNALEN."

ON December 11, 1847, Gustav Wiedemann was made Doctor of Philosophy of Berlin University with a thesis "De Novo quodam Corpore ex Urea producto." To celebrate the fiftieth anniversary of that event, the publishers of *Wiedemann's Annalen der Physik und Chemie* conceived the happy idea of printing a jubilee volume composed of special papers by the more regular contributors. The result is a collection of fifty-seven papers by a number of eminent men, including Kohlrausch, Nernst, Ostwald, Quincke, Drude, Warburg, E. Wiedemann, and others of equal distinction.

Four years ago, the golden jubilee of the *Annalen* was celebrated with a retrospect by Hermann von Helmholtz. These annals, with their lineal ancestors, *Poggendorff's and Gilbert's Annalen*, cover over a century of German physical science, and are a noble monument to German intellectual activity. No better jubilee gift could have been made to the veteran editor than this collection of choice fruits of his colleagues' labour. We subjoin some extracts which will indicate the nature and value of the work offered, regretting that space does not permit of more.

Reversal of the valve action in discharge tubes, by E. Hagenbach. When the gas in a discharge tube is only slightly exhausted, a conduction current is established at a certain pressure. At higher exhaustions a radiation of electricity sets in, chiefly from the kathode. This radiation takes place more easily from a point kathode than from a surface at the lower pressures, while at higher pressures the reverse is the case.—Torsion and magnetism, by P. Drude. The explanation of the connection between torsion and magnetism must be based upon the different amounts of internal friction encountered in longitudinal and transverse deformations respectively, giving rise to a peculiar orientation of the magnetic molecules.—The law of Wiedemann and Franz, by F. A. Schulze. This law maintains that the ratio between the thermal and electric conductivities is approximately the same for all metals. The author tested this for iron and steel rods, and found them to exceed the ratio, but not by so much as has been alleged by previous investigators.—Theory of galvanic polarisation, by A. Oberbeck. The determination of the galvanic polarisation in the original circuit is not an impossibility, as has been alleged. It may be closely approached along several lines. The capacity of a cell is a function of the polarisation. It becomes infinite when a certain superior limiting value of the polarising force is reached which produces the maximum polarisation. After that the polarised cell behaves like a constant cell opposed to the main current.—Magnetic after-effect, by I. Klemenčic. Instead of disappearing in strong fields, the magnetic after-effect, or the "viscous magnetic hysteresis," goes on increasing, but its percentage in the total magnetisation becomes less.—An acoustic thermometer for high and low temperatures, by G. Quincke. This thermometer is based upon the interference of a direct and reflected sound-wave of known length, produced by a standard tuning-fork. The wave travels along a tube surrounded by the temperature to be measured. A hearing tube is moved to and fro within the interference tube until a node is reached, indicated by the silence of the hearing tube. The displacement of the latter is read on a divided scale, and immediately indicates the temperature required.—Excitation of stationary waves by electric spark discharges, by F. Melde. An embroiderer's "gold thread" is made to vibrate between the knobs of a battery of jars, somewhat on the principle of the electrostatic cells.—Magnetic susceptibility and atomic magnetism, by G. Jäger and S. Meyer. The authors have found an interesting new relation between the paramagnetic metals. They investigated the magnetic susceptibilities of the chlorides, sulphates, and nitrates of iron, nickel, cobalt, and manganese in aqueous solution at various temperatures. The metal was found to be the decisive element, the acid being without influence. The magnetic susceptibilities per gramme-atom of nickel, cobalt, iron, and manganese were as 2 : 4 : 5 : 6. The gap between 2 and 4 is probably filled up by chromium.—Stratified discharge in the open air, by Max Toepler. The author has succeeded in obtaining a distinctly stratified discharge at atmospheric pressures, which recalls the stratified anode light, by interposing in the path of the spark a semi-conducting plate of dry slate, granite, syenite, or basalt, and ballasting the discharge with a heavy water resistance. Between the bright surface on the kathode and the first stratum a sharp black space is seen, usually very narrow, which is analogous to the black kathode space, and tends to show that there is no fundamental difference between ordinary and vacuum discharges.—Magnetic images, by H. Jaeger. The method of magnetic images may be extended to the case of a constant current traversing a conductor in the neighbourhood of an iron plate. The field created by the current and by the iron plate is the same as if another conductor were placed at the geometrical image of the first conductor in the iron plate, and the latter were removed.—Heating effect of Röntgen rays, by E. Dorn. The author measured the heating effect produced on sheets of platinum or palladium contained in a glass vessel with an aluminium window. The vessel communicated with a Toepler pressure gauge, and the heat was measured by the expansion of the gas. The expansion obtained is much larger than would be accounted for by a dissociation of the gas.—Electroscopic detection of electric waves, by A. Toepler. Describes a modified electroscopic arrangement of great sensitiveness. Two upright metallic cylinders stand in a box with walls of glass and ebonite. One of the rods is connected with a rectilinear resonator, the other is put to earth. Any wave incident upon the resonator which produces sparks, sets in violent motion a fine aluminium wire suspended between the two cylinders, which conveys the discharge from one to the other. The aluminium wire is attached to a steel needle, which is just held suspended by its point by a permanent magnet.—Counter electromotive force of aluminium, by V. von Lang. It is well known that in an aluminium-carbon electrolytic cell a current with a voltage under 22 will only pass in the direction carbon-aluminium, and this has been utilised for the electro-chemical rectification of an alternate current. Similarly, in an arc with two aluminium electrodes, a counter E.M.F. of some 19 volts is developed. An arc with one electrode of aluminium and one of carbon allows the current to pass with greater ease from aluminium to carbon, which is just the reverse of what happens in the cell.—Influence of magnetism on the strength of electric vacuum discharges, by A. Paalzow and F. Neesen. The discharge was produced by a constant high-potential battery. When the lines of force acted across the path of the current, the latter was always enfeebled, and sometimes broken. When they acted along the path, the magnetic field acted like an increase of pressure of the gas, delaying both the setting-in of the discharge and its extinction in the course of exhaustion.—Relation between the positive light and the dark kathode space, by E. Wiedemann. When a positive wire anode is brought into the dark kathode space, the resistance of the intervening gas is not lessened but increased. The positive light bends back until it merges in the negative glow. The same thing happens when the anode is surrounded by a narrow tube. In every case, the discharge traverses the positive strata and the negative glow in succession before it enters the dark space.—Simple demonstration of the Zeemann effect, by W. König. An emission flame which can be placed in a strong magnetic field is viewed through an absorption flame and a dichroiscope or a doubly-refracting prism, which gives two images of the emission flame side by side. On making the field one of the images brightens up, owing to the length of its light waves being changed, and therefore no longer absorbed by the absorption flame.—Magnetic and electric wind, by O. Lehmann. Describes some curious cases of the modification of the path of an electric discharge by a magnetic field. An arc between a ring of carbon and a concentric rod of carbon may be made to spin round rapidly, and a comet-like appendage may be made to revolve round the kathode in an "electric egg."

MAN IN RELATION TO THE GLACIAL PERIOD.[1]

As there appears even now to be a doubt in the minds of some as to whether man reached Britain before, during, or after the time known to geologists as the "Glacial period," it might be well on the present occasion to re-examine some of the evidence which has been brought forward to prove the presence of pre-Glacial man, especially from those areas in Britain which are now admitted to contain Glacial deposits, or to have been overspread by ice and snow in the Glacial period.

The most important evidence yet obtained, is that which has been furnished by the ossiferous caverns in the glaciated areas; but the occurrence in the same areas of the remains of extinct mammalia, which are now admitted to have been contemporary with the Cave Man, buried under great thicknesses of Glacial deposits, must also have an important bearing on the question.

All the evidence tends to show that the so-called Tertiary and Quaternary periods merged gradually into each other, and were not separated by any great break in Britain. The higher mountains, before the close of the Tertiary period, must have been covered in part by ice and snow, and the so-called Glacial period can only have a chronological importance as indicating the increased intensity and climax of that cold condition gradually ushered in at the earlier time. For the same reason there is no marked and definite line separating the fauna of the Pliocene from that of the Pleistocene, for we find remains of the animals of the warmer period closely associated with those of the colder in the same deposits and under conditions which show clearly that they lived in those areas at the same time.

North Wales and the North-west of England.

It is generally admitted that during the latter part of the Pliocene period the mountains of North Wales stood at a considerably higher elevation than they do at present; therefore it is but natural to suppose that during that time the streams which flowed from them gradually deepened, widened, and also possibly carved out some of the pre-Glacial valleys. The Carboniferous limestone along the flanks of the mountains, which had at an earlier time been much broken and crushed by earth-movements, now suffered from the additional effects of subaerial action, and wide fissures and caverns were gradually formed in it. In time some of these, as the streams found outlets at lower levels, would be left comparatively dry, and would then be suitable for habitation by man and beast.

In nearly all those caverns where remains of the extinct animals and the implements of contemporary man have been found, there is some amount of sediment underlying the remains. This must have been left there by the streams or floods which also deposited the materal which filled up the narrow descending fissures, thereby making a fairly level floor to the caverns before occupation. This material in every case, unless where there is evidence of its having been subsequently disturbed, consists entirely of such local materials as would be brought down by the streams from the immediately adjoining higher ground. When the higher caverns were first occupied by hyænas it is probable that there was comparatively little ice or snow on the mountains, and many of the animals which lived in the valleys and on the plains extending from them were southern types. Gradually, however, as the cold increased, northern forms appeared on the scene, and a commingling of the two groups took place.

The geographical features in the west and north-west in later Pliocene times may be briefly summarised as presenting high mountainous areas in Wales, Cumberland, the South of Scotland, and in parts of Ireland bordering the Irish Sea and St. George's Channel, with extensive plains traversed by great rivers in the areas now submerged, between the west coast of England and Wales, and Ireland. The conditions here were then in every way suitable to form feeding-grounds for herds of the great mammalia, and indeed such as could never have been repeated afterwards in these areas either in late Glacial or in post-Glacial times.

Animals from the south-east could reach these north-western plains across Cheshire and the lowlands in the centre of England, and others from the south by the plains on the west coast of Wales. In this way northern and southern animals would in a sense freely commingle and be afterwards driven to more southern areas together as the cold increased, and the conditions became more and more unsuitable to them. At first, in the mountains bordering these plains, when only their higher parts were covered with ice and snow, glaciers would occur only in the higher valleys; but as the cold increased they would become confluent with those from adjoining areas, and in time reach the plains and there coalesce to form, perhaps, as has been suggested, one vast sheet reaching across from England to Ireland. Most of the animals, ere the last stage had been reached, would, of course, have disappeared from those parts towards more suitable southern areas.

That the foregoing is, in brief, the history of the incoming of the Glacial period in the north-west is evident from the deposits which have been found in and about the caverns, and in sections at various points on the hills, in the valleys, and around the coast of North Wales.

Wherever the earlier materials have been preserved, especially at high levels, they are seen to consist entirely of local materials, *i.e.* such as would be derived from the immediate neighbourhood, or carried down by streams or ice from the adjoining higher ground.

Over this, and partly mixed up with it in the areas not reached by the northern ice, there is an admixture of materials from other Welsh districts and in the valleys opening out to the north, and along the coast there is the further admixture of erratics from northern areas. It is an interesting fact that the boundary-line in the Vale of Clwyd reached by the northern erratics is very little more inland than the area in which the caverns we have explored occur.

Of the history of the subsequent changes I need say but little; but it seems to me that there is fairly good evidence to show that a considerable subsidence did take place towards the close of the Glacial period, and that this was afterwards followed by a certain amount of upheaval in the same areas.

The presence of such thick deposits of drift, below the level of the sea, at the entrance to the Vale of Clwyd, with bones of the early Pleistocene mammalia at the very base, is a fairly sure test of a stage of subsidence, and it is also difficult to account for the finding of numerous foraminifera in clays at a height of about 200 feet above present sea-level around the coast unless alternating movements of subsidence and upheaval took place. The marine sand with broken shells at high levels, formerly looked upon as sure evidence of subsidence to that depth must not be relied upon too confidently, as in no case has it been clearly shown that the organisms lived in the positions where the shells are now found. In some cases there are also fairly clear indications that the deposits have been transported to fairly high levels by ice which had passed over and scraped up materials from the sea-bottom.

---

[1] "Evidences of the Antiquity of Man furnished by Ossiferous Caverns in Glaciated Districts in Britain." Abstract of Presidential Address to the Geological Society, delivered at the annual meeting, February 18, by Dr. H. Hicks, F.R.S.

It seems safer, at present, from the evidence which has been brought forward of late years by so many competent observers, to assume that towards the close of the Glacial period the earth-movements produced changes only of a few hundred feet rather than the greater depression and upheaval suggested by the earlier geologists.

Early Pleistocene Conditions on the East Side of England.

On the east side of England, as on the west, there were at this time great plains, extending out from the valleys, and much of the area now covered by the North Sea must have been dry land where northern and southern animals commingled. That this was the case is shown by the finding of their remains in close association in the hyæna-den at Kirkdale and in other caverns in Yorkshire. Prof. Phillips many years ago came to the conclusion that the Kirkdale Cave was occupied in the "pre-Glacial condition of the land which is now Yorkshire," and he also maintained that the lowest Hessle Gravels which rest upon the chalk, and which contain mammoth and other remains, and are covered by Boulder-clay, are pre-Glacial in age.

Mr. G. W. Lamplugh's careful researches seem to show clearly that the Sewerby Gravels, which have yielded so many Pleistocene remains, are at the base of the glacial series in that area. He says of the fauna at the base of the drift at Sewerby:—"It is essentially the fauna of the Kirkdale Cave."[1] In his conclusions, given in the same paper, when referring to the physical conditions prevailing in the area during the formation of the drift-deposits, he says:—"At a period not long anterior to that of the glaciation of the coast, Flamborough Head was in existence as a bold promontory jutting out into a sea whose level was slightly above that of to-day. Most of the mammals characteristic of the Glacial period were already living, and tenanted the interior in large numbers. The climate was moist and not very severe, the prevalent winds, as shown by the sand-dunes of Sewerby, being from the west or south-west. After the land had remained for a long time stationary, a slow elevatory movement set in, and the climate became much colder; so that the Chalk-surface was disintegrated by frost and eroded by sudden floods, which spread thick beds of muddy detritus over much of the low or slightly sloping ground in the vicinity. Meanwhile the bed of the North Sea was being rapidly filled with ice through the great extension of the Scandinavian glaciers, till at length the Scotch and Scandinavian ice coalesced, and what remained of the North Sea was well-nigh ice-locked."

Although some southern forms whose remains have been discovered in the forest-bed on the Norfolk coast do not appear to have reached much further north than that area, this does not, in my opinion, make it in any way certain that even these were not, in part at least, contemporaneous with the so-called mixed early Pleistocene fauna of the more northern districts. It is also an important fact that many of the most characteristic animals whose remains have been discovered in the caverns in North Wales and Yorkshire are now always included in the fauna of the forest-bed. The position of the forest-bed of Norfolk under high cliffs of Boulder-clay is also very similar to that of the lower deposits near the entrance to the Vale of Clwyd, containing Pleistocene remains and trunks of trees in like manner covered over by a great thickness of Glacial drift. It may also be compared with the forest-bed in Holyhead Harbour, buried under "stiff blue clay," in which two perfect heads of the mammoth were found when the excavations for the railway were made in 1849. The tusks and molars were buried two feet deep, in a bed of peat three feet thick, with stumps and roots of trees.[2]

It may be well to mention that the following mammals, whose remains have been found in caverns in North Wales, Derbyshire, and Yorkshire are now generally given as forming a part of the fauna of the Norfolk forest-bed, and that several of them, such as the glutton, musk sheep, and mammoth must be considered typically northern animals. The list is taken from those published by Prof. Boyd Dawkins or Mr. E. T. Newton, and there are animals which may be classed as characteristic of arctic, temperate, and hot climates. Animals whose remains have been found in caverns in association with human implements, and which are stated also to occur in the Norfolk forest-bed, viz. *Elephas antiquus*, *E. primigenius*, *Hippopotamus amphibius*, *Equus caballus*, *Sus scrofa*, *Bison*, *Ovibus moschatus*, *Cervus elaphus*, *Cervus capreolus*, *Megaceros*, *Machairodus*, *Canis lupus*, *C. vulpes*, *Hyæna crocuta*, *Ursus speleus*, *Gulo luscus*, *Lutra vulgaris*, *Arvicola amphibius*.

When the cold increased, the animals on the East coast, as on the West side, were driven further and further south, and those least able to bear the increased severity of the climate were the first to migrate from the various areas. The southern forms may consequently be looked upon, for the areas in which they have been found, as the oldest fauna; but it is reasonable to suppose that they were contemporary with the more northern forms, which at that time lived in other districts where the conditions were more suitable to them. When the northern forms reached the South of England, the conditions in and around the mountainous districts were such that few animals could remain there, as most of the valleys and plains had become buried under ice and snow, and they would have to seek feeding-grounds outside these areas. It is to this period that we must assign the remains of the mammoth and rhinoceros which are so abundantly found on the old land-surfaces on the north of the Thames, usually hidden under great thicknesses of drift, as in Endsleigh Street, and in other places in Middlesex. Here, and in some areas further south, they could have lived during most of the Glacial period until at last driven away, when the valleys and plains became covered with vast sheets of water, due in part probably to subsidence, but largely owing to the gradual melting of the ice and snow further north. Whether the mammoth and rhinoceros continued to live much longer in some parts of the South and South-west of England there is very little evidence at present to show. The supposition, however, held by some that they returned to the glaciated areas after the Glacial period had passed away does not seem to me in any way probable, for hitherto their remains have only been found either under or in the drift, and not above it, excepting when they have been washed out from the earlier deposits.

Summary.

The evidence which has been obtained from ossiferous caverns at high elevations in the glaciated areas shows conclusively that the remains of the extinct mammalia found in them must have been introduced before any of the Glacial deposits now in or upon them could have been laid down, therefore either before or so early in the Glacial period that there could not have been at the time any considerable amount of snow on the neighbouring mountains, or glaciers even in the higher valleys.

From caverns in glaciated areas in North and South Wales, where palæolithic implements have been found in association with remains of the extinct mammalia, facts have been obtained which make it certain that the implements were those of man living at the same period as the extinct animals in those areas, and therefore of pre-Glacial age. It has also been shown that as the cold increased the higher valleys became filled with glaciers, and the caverns became uninhabitable. That afterwards, as the snow-line and glaciers descended lower and lower, some of the caverns were subject to inundations, which not only disturbed and rearranged the deposits previously in them, but wholly or partially filled them up with local materials. That in the Vale of Clwyd, North Wales, the local glaciers gradually coalesced with those from the western and northern areas, and a mixed material was distributed over the district to a height of over 600 feet, burying the ossiferous caverns beneath it. During this time also water re-entered some of the caverns, redisturbing in part the earlier contents and depositing some of the mixed drift over that previously in the caverns.

While these caverns were occupied as dens by the hyænas, northern and southern animals commingled in the valleys and on the great plains reaching out from them to the area now covered by the Irish Sea.

From numerous examinations made of undisturbed Glacial deposits in Wales, the North of England, and Scotland, it has also been proved very clearly that the extinct mammalia, whose remains are found in association with the implements of Palæolithic Man in caverns, must have lived there before those deposits had been laid down, as their remains always occur at the base or in the lower parts of the drift, and never above it. Further, there is not a particle of evidence to show that the extinct mammalia ever revisited those areas after the close of the Glacial period.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. W. D. Niven, F.R.S., has been appointed an Elector to the Plumian Professorship of Astronomy, and Sir W. H. Broadbent an Elector to the Downing Professorship of Medicine.

Mr. J. Graham Kerr, of Christ's College, well known for his adventurous journeys as a naturalist in South America, has been elected a Fellow of Christ's College

---

PROF. G. B. HOWES, F.R.S., is to receive the honorary degree of LL.D. from the University of St. Andrews.

WHEN a shorthand writer, only familiar with the phonographic signs of the vocabulary of every-day life, endeavours to take notes of a science lecture, he soon finds his deficiencies. To exercise pupils in the art of making shorthand notes during lectures, Mr. Percy E. Kingsford, of Dover College, has inaugurated a course of special science lectures (with experiments and other illustrations) as nearly as possible of the character of those which his students will receive when they pass to the science or technical college, or medical school. The practice thus afforded the students will be very valuable. Science lecturers who have suffered at the hands of newspaper reporters, and have had ideas fathered upon them which they would be the first to repudiate, will join with us in wishing that all phonographers would undergo a similar course of training in reporting scientific lectures. It is very difficult to obtain an accurate verbatim report of the speeches made at any meeting where scientific subjects are discussed.

AN open competitive examination for the entry of engineer students in Her Majesty's Navy, and for the entry of students in Naval Construction, will shortly be held. The opportunities offered by this branch of the naval service are not so widely known as they ought to be. Candidates for the studentships must not be less than fourteen, nor more than seventeen years of age. A competitive examination is held every year in April, the subjects being arithmetic, writing from dictation, composition, grammar, French (or German or Italian), Latin, elementary physics and chemistry, geography (including physical geography), algebra (including quadratic equations), Euclid's Elements (Books I.-IV., VI., and definitions of V.), and freehand drawing. Successful candidates go to the admirable Engineering College—the Royal Naval Engineering College—at Keyham, Devonport, and there receive, under Prof. A. M. Worthington, F.R.S., a thorough course of instruction in the various branches of engineering science, while at the same time they receive practical training in the Dockyard. The best of means is thus afforded the students of acquiring the groundwork of the theoretical and practical knowledge required of a modern naval engineer. During the five years which the students have to serve at Keyham, the parents or guardians are required to pay the sum of 40*l*. per annum ; but for this the students receive an excellent education, as well as board and lodging and medical attendance. At present, a large number of the students come from naval ports, such as Portsmouth and Devonport ; but if the studentships were more widely known, doubtless many places which are now but rarely represented would send in candidates for them.

THE jubilee of Queen's College, London, will be celebrated during the first week in May. The College was founded in 1848, and incorporated by Royal Charter in 1853. It was the pioneer of the movement for the development of educational facilities for women, and in the list of past and present professors and lecturers the names of a number of distinguished men of science occur. Among the names of Fellows of the Royal Society who have served the College, but have now passed away, we notice D. T. Ansted, Edward Forbes, W. B. Carpenter, and W. A. Miller ; while among the present Fellows whose names figure in the list are Prof. H. G. Seeley and Prof. J. M. Thomson. The College curriculum is divided into three parts for students of different ages, and in each of the departments the development of mental powers without undue strain is the object of the instruction, preparation for public examinations being given but secondary consideration. A college which in these days does not shape its curriculum according to the syllabuses of examining bodies deserves encouragement ; and Queen's College should, therefore, not lack responses to the appeal which the Council has issued for means to enlarge and generally improve the premises, so as to meet the increased requirements of modern education. Among the additions will be a large lecture-room for science lectures. The estimated cost of the whole work will exceed 7000*l*., of which sum more than 3000*l*. have still to be raised. The College has no endowment for such purposes, and it appeals for help to all who recognise the important share it has taken in the development of women's education. The object is a worthy one, and it is to be hoped that the greater portion of the sum required will be raised before the jubilee celebration in May. The Lady Resident would be glad to receive the names and addresses of old students, in order to send invitations for the forthcoming event.

A COPY of the general report on public instruction in the North-western Provinces of Oudh, for the year 1896-97, has been received. The institution of a Faculty of Science in the University of Allahabad is referred to, and mention is made of various other efforts to encourage the study of science. What appears to be more needed than anything else is a more liberal supply of apparatus for experimental purposes. It is discreditable that Prof. Murray, who has charge of the physical science classes in one of the Government colleges, should have to report : "We have about nine metre scales in the laboratory ; no two are exactly alike, and which (if any) is correct it is impossible to say. Similarly the variations in our various measures of resistance one with another are in some cases as much as 30 per cent. of the whole." But notwithstanding this unsatisfactory state of things, the report shows that means are being taken to strengthen the colleges on the science sides, both by providing additional apparatus and by increasing the accommodation. The subjoined extract from the report shows that the development is taking place on the right lines :—"Steps have been and are being taken to make school education less bookish, and more practical. An English writer, after thirty years of teaching, has recently urged that geography should be taught mainly by means of map drawing ; that text-books should be used chiefly as books of reference ; that lessons in arithmetic and geometry should include practical work in measurement ; that in teaching modern languages the written or spoken language should be made the basis, and instruction in grammar founded upon it ; that mastery of English does not come by grammar and analysis, but by observation and practice ; and that true science consists in a scientific habit of mind, and not in a knowledge of scientific facts. These views appear to me to be fully applicable to India, and as a matter of fact similar aims have been kept in mind latterly in these provinces, particularly as regards geography, arithmetic, geometry and science. The idea of using text books in most subjects as books of reference is, however, so contrary to the notions of masters and boys that it will be long before the new revelation is generally received."

SCIENTIFIC SERIALS.

American Journal of Science, February.—The 27-day auroral period and the moon, by H. H. Clayton. Auroras were observed in 1895 on January 19, February 15, March 14, and April 10, *with no intermediate cases*. The probability of an accidental distribution in this manner is only 1 in 19,683. This period is probably due to the varying position of the moon north and south of the equator. When the moon's period is counted from its greatest northern position, there is a maximum on the 14th day, which coincides with the moon's greatest southern declination. There are minima on the 6th and 20th days, and a secondary maximum on the first day. The moon is an electrified body, charged negatively like the earth, and the potential gradient at the earth's surface depends upon the moon's position in the heavens.—Some products found in the hearth of an old furnace upon the dismantling of the Trethellan tinworks, Truro, Cornwall, by W. P. Headden. The ores smelted in this furnace for about 100 years were the usual Cornish tin-ores carrying some arsenopyrite, which is cobaltiferous, and accounts for the cobalt in the samples. The chief products described are stannous sulphide, SnS, with some iron, a new iron arsenide, $FeAs$, an arsenide of tin, Sn_6As, and stannic oxide, or an artificial "wood tin." The latter was an irregular mass weighing about one and a half pounds. There was a central portion of metallic tin running lengthwise through the mass. It was probably formed by slow oxidation of a block of tin, but whether that was due to simple air and moisture or to other hot gases cannot now be determined.—Kant as a natural philosopher, by G. F. Becker.

Kant's fame as a metaphysician has completely overshadowed his reputation as a physicist; but all his earlier papers were on physical subjects, such as the theory of winds, the earth's rotation period, the rings of Saturn, and, best-known, the nebular hypothesis of the universe. His great object in life was to discourage visionary speculation and to reduce all subjects to the confines of reason. Where Newton had in some cases to postulate the direct intervention of the Creator, Kant based his explanation upon known physical laws. If he had known the laws of thermodynamics, his nebular hypothesis, which only fell short in that respect, would have completely anticipated Laplace.—The islands and coral reefs of the Fiji group, by A. Agassiz. This is an extract from a letter dated Suva, Fiji Islands, December 15, 1897, describing a cruise in the Australasian twin-screw steamer *Yaralla*. The writer says: The great variety of causes which have been active in shaping the present physiognomy of the reefs and atolls of Fiji shows the impossibility of assigning any one factor, like subsidence for instance, as is done by Dana and Darwin, as the single cause for the formation of the many different kinds of atolls and barrier reefs to be found in the Fiji group. The formation of the great barrier reef of the southern shores of Viti Levu is due to causes very similar to those which have given to the northern coast of Cuba between Nuevitas and Matanzas its present physiognomy.

Symons's Monthly Meteorological Magazine, February.—Meteorological observations at Camden Square, London, N.W. There are few records day and night for forty years without a break, and no station with suitable exposure in London which has been at work so long. We are glad to see that Mr. Symons intends to give a series of tables showing the results of his observations for each month, and the present number, being the first of a new volume, contains those for January 1858-97.—Warmth, dryness, and high barometer in January 1898. A number of notes are quoted upon the above subjects; the table above referred to shows that, for London, the features of 1898 are: barometer almost unprecedently high; mean dry bulb temperature, 0·05° above 1884, and therefore the highest on record; minimum in air and on grass, 0·6° and 0·5°, respectively, above the highest previous records, which were in 1875 and 1884; rain, only about a third of the average, but more than twice that of 1880.—In the Conway Valley geraniums were found in blossom out of doors.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 3.—"Comparison of Oxygen with the extra Lines in the Spectra of the Helium Stars, β Crucis, &c.; also Summary of the Spectra of Southern Stars to the 3½ Magnitude and their Distribution." By Frank McClean, F.R.S.

In a previous paper read before the Society on April 8, 1897, it was suggested that the special lines present in spectra of the first division of helium stars (Type I., Division I*a*) might possibly be due to oxygen.

The indications in the spectra of the northern stars that these extra lines are due to oxygen are slight, as the lines at best are indistinct. Among the southern stars, however, there are several in the spectra of which these lines are better defined, and there is one, viz. β Crucis, in which they are very fairly defined.

Upon the plate which accompanies the paper a series of photographs of stellar spectra are reproduced. The lines are drawn out by themselves below the spectrum of β Crucis. They are then compared directly by juxtaposition with a drawing of the spectrum of oxygen. The close similarity of the whole grouping of the two spectra as they appear on the plate admits of little doubt that the extra lines actually constitute the spectrum of oxygen.

The spectrum of γ Argus is given on the plate in order to identify it as a helium star. It contains two crucial lines of helium. The Wolf-Rayet stars, of which it is the principal example, are thus classified as helium stars.

A summary of the spectra of 116 stars to the 3½ magnitude in the Southern Hemisphere is given. They were photographed between May and October last with an object-glass prism, mounted in front of the Cape astrographic telescope. The photographic spectra are classified on the same system as in the previous paper. The table of distribution for the whole sphere by areas and classes is given.

There are in all 89 helium stars (Division I.), distributed 71 in the galactic zones and 18 in the galactic polar areas, the areas being equal.

The 81 stars in Division II., the Sirian stars, and Division III., the Procyon stars (which along with Division I. constitute Secchi's Type I.) are rather irregularly distributed throughout the sphere. To the extent of the observations there is no condensation of stars of Divisions II. and III. in the galactic zones as there is in the case of stars of Division I.

The 106 stars in Divisions IV. and V. (II. and III. of Secchi's types) are fairly evenly distributed throughout the sphere.

The general distribution of the types of spectra throughout the sphere to the extent of the observations bears out generally the conclusion that stars with spectra of the more advanced types, in order of development, are evenly distributed in space. Also that stars with spectra more recent in order of development are mostly congregated in the galactic zones. The helium stars of Division I. are predominant in the Southern Hemisphere, being congregated in the lower or southerly halves of the galactic zones. They include 48 stars out of a total of 94 stars in those areas. They are also more closely congregated in the vicinity of the galaxy than is the case in the northerly halves of the galactic zones. In the contiguous constellations of Musca, Crux, Centaurus, Lupus, and Scorpio there are 27 helium stars out of a total of 36 stars included in the tables.

February 17.—"Upon the Structure and Development of the Enamel of Elasmobranch Fishes." By Charles S. Tomes, M.A., F.R.S.

The nature of the hard polished outer layer of the teeth of this group of fishes has been from time to time a subject of discussion, some authors holding that it is enamel, whilst others deny its claim to be so styled.

The general conclusion arrived at by the author is that, just as the whole teeth of the Elasmobranchs present the simplest known form of tooth development, so do they also present the first introduction of enamel as a separate tissue.

In its first introduction it was a joint product, made under circumstances which almost precluded any slow and gradual formation of an outer layer upon the teeth; but in the further specialisation of teeth in reptiles and mammals the tooth germs sink more deeply into the submucous tissue, and are protected for a much longer time.

The enamel organs become more specialised, and finally take upon themselves the entire work of enamel building, manufacturing both the organic matrix and furnishing it with lime salts, as unquestionably happens in mammals.

And if these conclusions be correct, it would be quite justifiable to call it enamel, even though the dentine papilla has had a share in its production.

Geological Society, February 2.—Dr. Henry Hicks, F.R.S., President, in the chair.—The President announced that Dr. Charles Barrois, Secretary of the Organising Committee of the VIIIth International Geological Congress, which will be held in Paris in 1900, would shortly come to London to invite the Geological Society to the Congress, and to consult the Fellows with regard to the proposed excursions and the subjects of discussion.—"Contributions to the Glacial Geology of Spitsbergen," by E. J. Garwood and Dr. J. W. Gregory. The extent of glaciation of Spitsbergen has been exaggerated, for there is no immense ice-plateau, but normal glaciers with some inland sheets and Piedmont glaciers. These differ from Alpine glaciers, as they are not always formed from snow-fields at the head, and though some of the glaciers (as the Baldhead Glacier) have tapering snouts in front, most have vertical cliffs. Chamberlin's explanation that the latter are due to the low angle of the sun is insufficient, and they seem to be caused by the advance of the ice by a rapid forward movement of its upper layers. The ice of these upper layers falls off and forms talus in front, over which the glacier advances, carrying detritus uphill with it, and producing a series of thrusts. The Booming Glacier illustrates cases of erratics carried in different directions by the same mass of ice. The deposits of the Spitsbergen glaciers are of four types: (1) moraines of Swiss type; (2) those formed mainly of intraglacial material; (3) those formed of re-deposited beach-material; (4) deposits of glacial rivers, and re-assorted drifts. The materials of the second are subangular and rounded; scratched and polished pebbles and boulders are abundant, and the fine-grained matrix, which is frequently argillaceous, is often well-laminated and false-bedded. Some of these drifts are stratified, others unstratified, and contorted drifts occur. This type of moraine is remarkably like some British boulder clay. The third class is sometimes formed by land-ice, at other times beneath the sea; the latter shows stratification. The superglacial and intraglacial streams, so far as seen, were usually clear of drift. Under the fourth head an esker in a tributary of the Sassendal is described. The direct geological action of the marine ice is of four kinds: transport of material, contortion of shore-deposits, formation of small ridges of boulder-terraces above sea level, and striation, rounding, and furrowing of rocks along the sea-shore. Traces of former glaciation are described in the case of the Hecla Hook beds, and of certain beds of late Mesozoic or early Cainozoic age in Bunting Bluff. Under the head of general conclusions the authors state that they have discovered no certain test to distinguish between the action of land-ice and marine ice; that there is no evidence to prove that land-ice can advance far across the sea; and that there is evidence, which they regard as conclusive, of the uplift of materials by land-ice. They note that the mechanical processes connected with the advance of the glaciers are of three kinds. All the material seen transported by the glaciers was superglacial or intraglacial, and not subglacial Some striation of intraglacial material is caused by differential movement of different layers of ice. The advance and retreat of the Spitsbergen glaciers is very irregular, and apparently due to local changes. The observations of the authors support the views of those who ascribe a limited erosive power to glaciers. Lastly, the theory that glacial periods occurred as a consequence of epeirogenic uplifts receives no support from Spitsbergen.—An interesting discussion followed, in which Sir Martin Conway, Prof. Bonney, the Rev. Edwin Hill, and Mr. Marr took part. Mr. P. F. Kendall said that the paper would mark a distinct epoch in British glacial geology. Hitherto, one body of geologists had attributed the drift-deposits of Britain to the agency of land-ice, while another had invoked the agency of the sea. The latter had argued that glaciers cannot move uphill, that they cannot transport materials from lower to higher levels, that glaciers cannot gather up materials over which they are moving, and that, even if they could pick up shells they would grind them to powder—"On a Quartz-rock in the Carboniferous Limestone of Derbyshire," by H. H. Arnold-Bemrose. The paper describes the occurrence in the field and the microscopic structure of a rock consisting essentially of quartz, which is found in the mountain limestone in several localities. It occurs in irregularly-shaped bosses and veins, and shows no signs of stratification. The author considers that the quartz-rock is not a gritty limestone, altered by the growth of crystalline quartz around the detrital grains, but that it is a limestone replaced by quartz.

Mathematical Society, February 10.—Prof. Elliott, F.R.S., President, in the chair.—Lieut.-Colonel Allan Cunningham, R.E., read a paper entitled "On Aurifeuillians." These are defined as the *algebraic prime factors* of two functions, viz.: of $(X^{2n} + Y^{2n})$ when $2nXY = \square$, and of $(X^n + i^{n+1}. Y^n)$ when $nXY = \square$, where n is *odd*, and $i = \sqrt{-1}$. Their salient property (discovered by Mr. Aurifeuille, of Toulouse) is that they are *algebraically* resolvible into two factors (say L, M). Also L, M are expressible in the same 2^{ic} forms as their product-function. The quotient of one Aurifeuillian by another of the same order has the same properties. The properties of the two Aurifeuillians of orders 2 and 3, viz.:

$$(x^4 + 2^2y^4) \text{ and } (x^6 + 3^3y^6) \div (x^2 + 3y^2),$$

were stated at some length. The application to Fermat's numbers $(2^{4\nu+2} + 1)$ and $(3^{6\nu+3} + 1)$ was given, and a table of the factorisation thereof into *prime* factors was given, extending (with gaps) to $(2^{210} + 1)$, $3^{105} + 1)$. In opening the discussion on the paper, Mr. Bickmore pointed out that Aurifeuille's formulæ, which were enunciated without complete proof by Lucas, might be completely proved by the theory of complex integers. Thus the formulæ express the algebraical prime-factor of $a^n - (-1)^{\frac{n-1}{2}} b$, of n as the difference of two squares, when n is an uneven integer, and $\frac{ab}{n}$ is a perfect square. But the algebraical prime-factor is the norm of the binomial n^{ic} integer

$$a - (-1)^{\frac{n-1}{2}} b\rho^2,$$

which, when

$$a = x^2 \text{ and } b = ny^2,$$

is equal to

$$\left\{x - (-1)^{\frac{n-1}{4}} y\rho\sqrt{n}\right\} \times \left\{x + (-1)^{\frac{n-1}{4}} y\rho\sqrt{n}\right\}.$$

Gauss's results give

$$(-1)^{\frac{n-1}{4}} \sqrt{n} = f(\rho),$$

a rational integral function of ρ; hence, finally,

$$N_n\left\{x^2 - (-1)^{\frac{n-1}{2}} ny^2\rho^2\right\} = N_n\{x - y\rho f(\rho)\} \times N_n\{x + y\rho f(\rho)\}.$$

The formulæ also express as the difference of two squares the algebraical prime-factor of $a^{2n} + b^{2n}$, when n is an uneven integer, and $\frac{ab}{2n}$ is a perfect square; in this case the final result is

$$N_n(x^4 + 4n^2y^4\rho^4) = N_n\left\{x^2 - 2ny\rho f(\rho) + 2(-1)^{\frac{n-1}{2}} ny^2\rho^2\right\}$$
$$\times N_n\left\{x^2 + 2ny\rho f(\rho) + 2(-1)^{\frac{n-1}{2}} ny^2\rho^2\right\}.$$

Kummer's tests show that if n be > 3, the absolute term in each of the complex integers is correctly fixed; hence, y being a factor of every term except the absolute term, if either Aurifeuillian factor be a prime, it has any prime factor of y as a residue of order n, when $n > 3$. The process also expresses complex n^{ic} integers with *more* terms than two, which are expressible in the form

$$x^2 - (-1)^{\frac{n-1}{2}} ny^2,$$

(x and y being themselves complex integers of order n) as the product of two complex n^{ic} integers.—The President (Lieut.-Colonel Cunningham, *pro tem.* in the chair) communicated a paper by Mr. J. E. Campbell on the transformations which leave the lengths of arcs on any surface unaltered. The object of the paper was to obtain the infinitesimal transformations which have the property of leaving unaltered the lengths of arcs on any given surface in space of $n + 1$ dimensions—that is, the transformations which leave $dx_1^2 + \ldots + dx_n^2 + dz^2$ invariant where $z = f(x_1 \ldots x_n)$. It is remarkable that this problem can be solved completely when $n > 2$, though not when $n = 2$. At the conclusion of the paper it is proved that if H is the Hessian of $f(x_1 \ldots x_n)$, then

$$H \div \left\{1 + \left(\frac{dy}{dx_1}\right)^2 + \ldots + \left(\frac{dy}{dx_n}\right)\right\}^{\frac{n+2}{2}}$$

is an invariant for such substitutions; this is a generalisation of the well-known theorem that the measure of curvature (on a surface in ordinary space) is unaltered by transformations which leave the lengths of arcs invariant.—Mr. Hargreaves made a short impromptu communication.

Zoological Society, February 15.—Dr. Albert Günther, F.R.S., Vice-President, in the chair.—A letter was read from Mr. Dudley Le Souëf, of Melbourne, containing a summary of some observations on the transfer by the mother of an embryo kangaroo (*Macropus giganteus*) by her mouth into her pouch.—A report was read, drawn up by Mr. A. Thomson, the Society's head-keeper, on the insects exhibited in the insect-house during the year 1897, and a series of the specimens was exhibited.—The Secretary exhibited a series of specimens of butterflies, which had formed part of a collection lately on view at the Dunthorne Gallery, in illustration of the mode of mounting employed in "Denton's Patent Butterfly Tablets."—Mr. W. P. Pycraft read the first of a series of contributions to the osteology of birds. The present part (of which the following is an abstract) related to the Steganopodes. The fact that in the tropic-birds, cormorants, gannets, and frigate-birds, all the toes are united by a common web, has led to the belief that these forms are closely related; they form the sub-order *Steganopodes* or *Totipalmatæ* of authors. A comparison of the osteology of the group confirms this opinion.—Dr. W. G. Ridewood read a paper on the skeleton of regenerated limbs of the midwife-toad (*Alytes obstetricans*). He demonstrated the possibility of the development, in the regenerated hind limb of the larva, of tarsal, metatarsal, and phalangeal cartilages identical in every respect with those of the normal limb.—Mr. G. A. Boulenger, F.R S., described a new species of sea-snake from Borneo, which he proposed to name *Hydrophis floweri*, after Mr. Stanley Flower, its discoverer. Mr. Boulenger also gave an account of the reptiles and batrachians lately collected by Mr. W. F. H. Rosenberg in Western Ecuador. Seventy-seven species were enumerated, of which twenty-three, viz. eleven reptiles and twelve batrachians, were described as new.

CAMBRIDGE.

Philosophical Society, January 24.—Mr. F. Darwin, President, in the chair.—A new method in combinatory analysis with applications to Latin squares and associated questions, Major P. A. Macmahon, R.A., F.R.S. The author applies the theory of symmetric functions to obtain solutions, hitherto unachieved, of problems in combinatory analysis associated with the question of Latin squares.—On Abelian functions in connection with two-dimensional fluid motion, H. F. Baker.—On the production of a cloud by the action of ultraviolet light on moist air, C. T. R. Wilson. If the light from an arc lamp be brought to a focus, by means of a quartz lens, within a vessel containing moist dust-free air, a bluish fog becomes visible in the course of a few minutes along the path of the light. The cloud particles remain in suspension for hours after the light has been cut off. The phenomenon is shown even in unsaturated air, but the faint blue haze which then develops takes much longer to form. When the radiation is not sufficiently intense to show these effects, a dense fog can still be obtained by bringing about slight supersaturation by expansion. These clouds, unlike those obtained by Tyndall (*Phil. Trans.*, 160, p. 333, 1870) and by Aitken (*Edin. Trans.*, 39, I. p. 15, 1897) by the action of light on various vapours, are due to the ultra-violet rays alone; for if a thin sheet of glass or mica (substances which are opaque to these rays) be interposed, not a trace of fog or rain is formed even when a high degree of supersaturation is brought about by expansion. It is possible that the small particles to which the blue of the sky is due are the result of this action of the ultra-violet rays, of which sunlight, when it first enters our atmosphere, doubtless contains a plentiful supply.—On the use of logarithmic coordinates in physics, J. H. Vincent. The paper divides all curves into "translatants" and "non-translatants." As examples of the former, Mr. Boys' chart of wave and ripple velocities is referred to, and an impedance chart is constructed. Non-translatants are not in general suited to this method of plotting. By suitable devices the logarithmic homologue of the equation for the propagation of waves on a frozen sea is drawn, although this is a non-translatant. The paper concludes with suggested uses of tri-dimensional logarithmic coordinates and semi-logarithmic coordinates.—On the diffuse reflection of Röntgen rays, Prof. J. J. Thomson. The paper contains the theory of the electromagnetic effects produced by suddenly setting an electrified body in motion. It is shown that a thin pulse of intense electromagnetic disturbance is generated which travels outwards with the velocity of light. The magnitude of the magnetic force at a point P due to the pulse is when the velocity w of the particle is small compared with the velocity of light equal to $we \sin \theta/2ar$, where $2a$ is the diameter of the particle O, e the change on the particle, r the distance PO, and θ the angle between OP and the direction of motion of the particle. Using the theory of the Röntgen rays given by the author in the *Phil. Mag.*, February 1898, the result just quoted is applied to find the intensity of the radiation scattered when Röntgen rays are incident on a collection of positively and negatively electrified bodies. The intensity of the scattered rays in a direction making an angle θ with the incident ray varies as $(1 + \cos^2 \theta)$. So that the intensity of the scattered light when $\theta = 0$ would be twice that when $\theta = \pi/2$. Photographs taken by the scattered rays in these two positions showed that there was little, if any, difference of intensity in these directions. This result indicates that the scattered Röntgen radiation is probably more nearly allied to fluorescence than to the scattering of light by small particles. Experiments were made on the absorption of the light diffusely "returned" (to use Sir George Stokes' phrase) from lead and platinum by thin sheets of platinum and red lead; these showed that there was no strong selective absorption by thin platinum of rays scattered from platinum, or by lead of rays scattered from lead. A mathematical investigation is given to show that in the case of rapidly damped radiations selective absorption would not be exhibited.

PARIS.

Academy of Sciences, February 14.—M. Wolf in the chair.—On certain singular examples of successive approximations, by M. Émile Picard.—On the masses of the planets, by M. E. Roger.—Remarks on a note by M. Anceaux. Of the three laws given in this note, the first only is rigorously exact, the second is an approximation, and the third a consequence of the two others.—*Résumé* of the solar observations made at the Royal Observatory of the Roman College during the second half of 1897, by M. P. Tacchini. Observations are given for the distribution of sunspots, protuberances, and faculæ.—On the extension of the decimal system to the division of the day and the circle; advantages and practical methods, by M. J. de Rey Pailhade.—On the singular Abelian functions, by M. G. Humbert.—On some general algorithms, and on iteration, by M. Lémeray.—On the surfaces which admit an infinite, discontinuous group of birational transformations, by M. P Painlévé.—Deformation of metals, by M. Mesnager.—Direct measurement of the period of the Hertzian oscillations, by M. L. Décombe. Photographs of the explosive spark from a revolving mirror showed that it is possible to fix on a gelatino-bromide plate oscillations of which the period is less than a five-millionth of a second. The necessary conditions were a very high velocity of rotation of the mirror, the employment of a collimating lens, in the focal plane of which the spark is placed, of very small focal length. The results obtained confirmed the theory of Poincaré and Bjerknes, according to which the radiations emitted are of one wave length only.—Emission of secondary rays in air under the influence of the X-rays, by M. G. Sagnac. It is shown experimentally that air through which the X-rays are passing gives off secondary radiations capable of affecting an electroscope. This phenomenon is comparable to the emission of light by a liquid containing a small quantity of a fluorescent substance in solution during the passage of a luminous bundle.—On a new contact-breaker for induction coils, by M. V. Crémieu. The ordinary form of contact-breaker used in induction coils is attended with the inconvenience that the oppositely induced electromotive forces are not symmetrical. This difficulty is overcome by the apparatus described, but at the expense of a larger amount of energy, since to obtain a spark of a given length the electromotive force of the primary circuit must be double that required by the ordinary form.—On a crystallised hydride of dicamphene, by MM. A. tard and G. Meker The dry hydrochloride of terebenthene is fused and sodium added; a hydrocarbon $C_{20}H_{34}$ can be obtained from the product of the reaction. It is noteworthy as being one of the few terpenes obtainable in the crystallised state.—Action of cyanamide upon bromanil in presence of potash, by M. H. Imbert. The substance obtained appears to be the potassium salt of dicyanimino-dibromo-dioxyquinone.—Researches on organic phosphorus, by M. J. Jolly. The experiments given tend to show that phosphorus does not exist in the organic molecule in an unoxidised state.—The production of carbon monoxide in the blood after inhalations of chloroform, by M. L. de Saint-Martin. In attempting to confirm the statement of MM. Degrez and Nicloux that prolonged inhalation of chloroform produces carbon monoxide in the blood, the author finds that normal blood, treated in a vacuum at 40°, with an organic acid, also gives off small quantities of carbon monoxide.—On the oxydase of *Botrytis cinerea*, by M. J. Laborde. A study of the effect of this oxydase upon the fermentation of grapes, with especial reference to the decolorisation of the wine.—Tuberculosis and pseudo-tuberculosis, by MM. Bataillon and Terre. The authors have previously described a form of the tubercle bacillus capable of existing in cold-blooded animals, such as the frog. A third form of this bacillus, originally human, has now been obtained after a passage of three days in the frog. On solid media this form grows rapidly at temperatures between 12° and 48°, and is distinguished from the form previously described by three points: appearance of cultures, power of easily developing at high temperatures, and rendering beef-broth turbid. The colonies on the potato are brownish, and the bacilli are not stained by the methods of Gram or Ehrlich. Experiments on animals led to the conclusion that many cases of pseudo-tuberculosis are in reality true tuberculosis, having as a cause one of the numerous forms of Koch's bacillus.—The parasites of cancer and sarcoma, by M. F. J. Bosc. As a result of the examination of numerous tumours it was found that the abnormal formations foreign to the tissues could be grouped under five morphological types: microbial forms, granulations, cellular forms of very variable origin, encysted forms and sarcodic forms. All these forms exist in epithelioma, carcinoma and sarcoma, but the last-named contains especially the microbial forms and the granulations.—Remarks on the Bloch-appendices in the siluroids of genus *Aspredo*, by M. Léon Vaillant.—On the place of the sponges in classification, by M. Yves Delage.—Influence of the X-rays on germination, by MM. Maldiney and Thouvenin. From experiments upon *Convolvulus arvensis*, *Lepidium sativum*, and *Panicum miliaceum*, it would appear that the X-rays hasten germination.—The melanosis of the mandarin orange, by M. Trabut.—Detection and rapid estimation of manganese in plants and vegetable earths by a colorimetric method, by M. P. Pichard. The method is based upon the ignition of the ash with an alkaline carbonate, and subsequent formation of permanganate by the use of lead peroxide and nitric acid.—On the conglomerate of the Amône in the Swiss Ferret valley, by MM. L. Duparc and F. Pearce.—On the formation of anhydrite by the calcination of gypsum at high temperatures, by M. A. Lacroix.—On the origin of the overlapping layers in the region of Ubaye, by MM. W. Kilian and E. Haug.—On some phenomena of fluvial erosion and corrosion, by M. Jean Brunhes.

DIARY OF SOCIETIES.

THURSDAY, February 24.

Royal Society, at 4.30.—Meeting for Discussion.—Subject: The Scientific Advantages of an Antarctic Expedition. The Discussion will be opened by Dr. John Murray, F.R.S.

Institution of Electrical Engineers, at 8.—On the Manufacture of Lamps and other Apparatus for 200 volts Circuits: G. Binswanger, Byng.

FRIDAY, February 25.

Royal Institution, at 9.—The Theory of Colour Vision applied to Modern Colour Photography: Captain W. de W. Abney, C.B., F.R.S.

Institution of Civil Engineers, at 8.—The Problem of Train Resistance: C. E. Wolff.

SATURDAY, February 26.

Royal Institution, at 3.—The Structure of Instrumental Music: W. H. Hadow.

Physical Society (Eton College), at 4.—The Rev. T. C. Porter will describe (1) a New Theory of Geysers; (2) a New Method of Viewing Newton's Rings; (3) Experiments bearing on the Sensation of Light; (4) a Method of Viewing Lantern Projections in Stereoscopic Relief; (5) Winter Observations on the Shadow of El Teide, with a New Method for Measuring approximately the Diameter of the Earth; (6) Temperature of the Water of Niagara.

MONDAY, February 28.

Society of Arts, at 8.—The Principles of Design in Form: Hugh Stannus.

Royal Geographical Society, at 8.30.—The Annual Range of Temperature in the Surface Waters of the Ocean, and its Bearing on Oceanographical Problems: Dr. John Murray, F.R.S.

Institute of Actuaries, at 5.30.—The Relation of the Actuarial Profession to the State: J. Nicoll.

TUESDAY, March 1.

Royal Institution, at 3.—The Simplest Living Things: Prof. E. Ray Lankester, F.R.S.

Zoological Society, at 8.30.—On the Perforate Corals collected by the Author in the South Pacific: J. Stanley Gardiner.—The Myology of the Terrestrial Carnivora, Part 2: Prof. B. C. A. Windle and F. G. Parsons. On the Brain and some other Points in the Anatomy of *Bassaris*: F. E. Beddard, F.R.S.

Institution of Civil Engineers, at 8.—Papers to be further discussed: The Theory Design, and Practical Working of Alternate-Current Motors: Llewelyn B. Atkinson.—Dublin Electric Tramway: H. F. Parshall.

Röntgen Society, at 8.—Photographic Activity and Penetration of Röntgen Rays at Different Vacua: J. H. Gardiner.—Other Papers by Wilson Noble and Hall Edwards.—Mr. Isenthal will show some New Apparatus.

WEDNESDAY, March 2.

Society of Arts, at 8.—Kites: their Theory and Practice: Captain B. F. S. Baden-Powell.

THURSDAY, March 3.

Royal Society, at 4.30.—*Probable Papers*: The Relationship of Variations of the Ground Water Level to the Incidence of Malarial Fevers in Chotta Nagpur, Bengal: Dr. L. Rogers.—On the Depletion of the Endosperm of *Hordeum vulgare* during Germination: H. T. Brown F.R.S., and F. Escombe.—Experimental Observations on the Early Degenerative Changes in the Sensory End Organs of Muscles: Dr. F. E. Batten.

Royal Institution, at 3.—Recent Researches in Magnetism and Diamagnetism: Prof. J. A. Fleming, F.R.S.

Linnean Society, at 8.—On the Sense Organs of the Lateral Line in certain Fishes: F. J. Cole.—On the Occurrence of *Carex helvola* in Britain: G. C. Druce.—On Arctic Spiders from Franz Josef Land: Rev. O. Pickard-Cambridge.

Chemical Society, at 8.

FRIDAY, March 4.

Royal Institution, at 9.—Some Recent Results of Physico-Chemical Inquiry: Prof. T. E. Thorpe, F.R.S.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Andrée and his Balloon: H. Lachambre and A. Machuron (Constable).—*Year-Book of the Royal Society, No. 2, 1897–98* (Harrison).—Meteorology in Mysore, 1896: J. Cook (Bangalore).—Magnets and Electric Currents: Prof. J. A. Fleming (Spon).—Twenty-fourth Annual Report of the Local Government Board, 1894–95. Supplement: Inland Sanitary Survey, 1893–95 (Eyre).—Report of the Meteorological Service of the Dominion of Canada, 1890 and 1895: R. T. Stupart (Ottawa).—Storm and Sunshine in the Dales: P. H. ARCHIMEDES.

The Works of Archimedes. Edited in Modern Notation, with introductory Chapters by T. L. Heath, Sc.D., sometime Fellow of Trinity College, Cambridge. Pp. clxxxvi + 326. (Cambridge: at the University Press, 1897.)

THIS is a companion volume to Dr. T. L. Heath's valuable edition of the "Treatise on Conic Sections" by Apollonius of Perga, and the same patience, learning and skill which have turned the latter book into a delightful guide to early Greek geometry have been here applied to present in a most readable form the extant works of perhaps the greatest mathematical genius that the world has ever seen. The same general plan of editing has been followed in this book as in that of Apollonius, such condensation and modernisation having been introduced as is possible without alteration of the methods employed. We consequently now possess for the first time in English dress a reproduction of Archimedes' work, without addition or essential omission, from which have been removed the thorns and briars that have hitherto beset the path of the English student who would make himself acquainted with the methods invented and employed by the extraordinary genius of Archimedes in order to make those measurements which now-a-days are rendered easy only by the use of the integral calculus. Not the least deterrent of these obstacles have been the Doric dialect of parts of the original and the abbreviations and corruptions in which the text of the accessible editions abounds, so that hitherto the French translation by Peyrard, or that in German by Nizze, has been preferable for the purposes of study.

The volume itself is a handsome example of mathematical printing such as we are wont to expect from the Cambridge University Press, and it is most fitting that it should have been issued by that Press, since Torelli's standard edition (in Greek with a Latin version) was published by and at the expense of the sister University under the editorship of Prof. Abram Robertson, D.D., of Christ Church.

The book will do much to restore Archimedes to his proper place in the estimation of mathematicians; for, in spite of the admirable histories of mathematics that lie to our hand, Archimedes is scarcely known at all except as the discoverer of an important principle in hydrostatics, or the constructor of a spiral, or the inventor of a screw, or the destroyer of ships by the use of a mirror. Indeed it is but little known that in his books on Equilibrium he laid the foundation of theoretical mechanics, and that in his treatises on Floating Bodies he created the science of hydrostatics; that he it was who discovered $3\frac{1}{7}$ as a superior limit of the ratio of the circumference of a circle to its diameter, and $3\frac{10}{71}$ as a still closer lower limit; that to him we owe the quadrature of the conic sections and of the surfaces generated by their revolution, as well as the cubature of the volumes so formed; or that he was the author of a system of representing numbers up to that which would now be expressed by 1 with eighty thousand million millions of cyphers following it. What else he may have done we do not know for certain, as our information rests on vague accounts by later authors; but eight at least of his published works are lost, and these cannot but have shown the same originality and been marked by the same presentation of new truths as those which have survived, while none of them, or of those that we have, relate to his numerous mechanical inventions, of which in comparison with his mathematical speculations he seems to have thought meanly since, in Plutarch's words, he would not deign to leave behind him any written work on such subjects.

Not the least important part of this book is the introduction of 186 pages which precedes the 326 pages of text. This contains a very valuable discussion of the problems that attracted the attention of the early Greek geometers, and also a most interesting account of the various suggestions that have been put forward as to the mode in which Archimedes obtained certain results which he states without entering into details respecting them.

After a preliminary recital of the stories told of Archimedes by ancient writers, and a short account of the ingenious mechanical inventions they have attributed to him, Dr. Heath discusses the MSS. sources of the text that survive, and enumerates with slight details the principal editions of their text that have been published. From this we learn all that is really needful, though the Latin version with commentary made by Abbot Maurolycus in 1534-49, and published at Palermo in 1685 by Cyllenius Hesperius, also deserves notice. One might further remark that if the titles of the different editions are given at all in anything like fullness, they should be given with absolute exactness, and this is not done in any of the Latin versions save those of Torelli and Heiberg.

Then follows an excellent chapter upon the relation of Archimedes to his predecessors, and this is full of interest not only historically, but also as contrasting Archimedes' methods with those of others, and illustrating his extraordinary facility in the manipulation of proportions, a special instance of which is, in modern notation, the elimination of b, c, d from the conditions $a/b = b/c = c/d > 1$, $3d(a - c) = 5x(a - d)$, $(a - c)(2a + 4b + 6c + 3d) = 5y(a + 2b + 2c + d)$. Next comes a clear account of the Greek system of numerals and the Greek modes of performing arithmetical operations, more especially with reference to the approximations to the square roots of numerics which are not squares; but in this last matter there is plenty of room for conjecture, as not much direct information is available, and Dr. Heath gives a fairly exhaustive account of what has been written on the subject. The fifth chapter treats of the problems known as *νεύσεις*, which deal with the straight lines that have to verge towards a given point, and fulfil some other condition too; these have not much to do with Archimedes, but they are exceedingly interesting, and without their discussion a study of Greek geometry would be incomplete. The Greek methods of geometrically solving problems that practically involve cubic equations are next unfolded at length, and a discussion of the classification of problems and loci as plane, solid and (curvi-) linear completes a most interesting chapter. Finally Archimedes' anticipations of the integral calculus by an admirable extension of the method of exhaustion are considered, and copiously illustrated; and the introduction concludes with a most useful account of the mathematical terms and phraseology employed by Archimedes.

Dr. Heath's general treatment of the text is excellent, but there is one point on which we do not think that he has exercised a sound judgment. This is the renumbering of the propositions in three of the books, which renders reference to them a matter of entire uncertainty. Thus the celebrated Prop. 37 of Book I. on the Sphere and Cylinder, which gives $\frac{2}{3}$ as the ratio of the surfaces and of the volumes of a sphere and the cylinder that just contains it, appears in Dr. Heath's book as a corollary of Prop. 36, which is numbered 34; he further puts Props. 33, 43, 45, 46 as corollaries, and includes Prop. 1 in the introductory letter, thus reducing to 44 the 50 propositions of the MSS. In Book II. he treats Prop. 1 similarly, even though Archimedes himself, in the introductory letter to his work on Spirals (p. 152), mentions this proposition as the first of those which were proved in this book. In the book on Conoids and Spheroids he further puts as a Lemma what appears as Prop. 1 in all the Greek and Latin texts, so that the famed Prop. 12 on certain plane sections of these figures, the characters of which are said by Archimedes to be *φανεραί*, appears as Prop. 11, and Prop. 18 is put as the third part of Prop. 17 (numbered 16)—without any reason, since it is not an extension of, though deducible from, the other parts.

Complete as the book is, there is one addition that would be welcomed by all students, viz. a table of all the writers named, and of the approximate dates at which they flourished; this, if of easy reference, would be of great help when the relation of different geometers to any problem was under consideration. A larger number of references is also desirable in the interests of the student who is stirred to go to the fountain-head by his thirst for first-hand information. Thus the proofs on pp. liv–lviii of the above-cited Prop. 12 on Conoids and Spheroids are so introduced, especially in being contrasted with Zeuthen's, as to appear to be quite modern, while really being contained in Torelli's edition, and practically also in the earlier editions of Maurolycus and Rivaltus.

We feel much inclined to challenge Dr. Heath's rendering of Euclid's definition of a straight line in his note on p. 3, and to maintain the correctness of the ordinary version of it. The special point seems to us to lie in the word *ἐπί*, "on," the use of which seems to be due to the thought in the writer's mind of points marked by letters over the line; thus Aristotle ("Ethics," v. 4, 12) writes *ἴσαι αἱ* [*i.e. γραμμαί*] *ἐφ' ὧν* ΑΑ, ΒΒ, ΓΓ *ἀλλήλαις* where the sentence can only mean "the lines AA, BB, CC are equal to one another"; the words must therefore mean "the lines are equal over the two ends of which A and A, B and B, C and C are written," so that Euclid's *τὰ ἐφ' ἑαυτῆς σημεῖα* must mean "its own extreme points."

Such slight blemishes, however, or what we deem to be such, do not detract from the very great value of this work, and Dr. Heath deserves our grateful thanks for the labour he has expended upon it. It is a fitting addition to his former task; for as, to quote Charles, in Apollonius work we find the origin of the geometry of Forms and Situations as it is now developed, so in the present book we are introduced to the basis of the geometry of Measurement which has demanded a new calculus for its perfection.

R. E. B.

A NEW TEXT-BOOK OF EXPERIMENTAL PHYSIOLOGY.

The Essentials of Experimental Physiology. For the use of Students. By T. G. Brodie, M.D., Lecturer on Physiology, St. Thomas's Hospital Medical School. Pp. xiv + 231. (London: Longmans, Green, and Co., 1898.)

THIS volume appears in the same series as two books already well known to the medical student of this country, viz. Schäfer's "Essentials of Histology" and Halliburton's "Essentials of Chemical Physiology." It is bound uniformly with these two volumes, but on opening the books all resemblance disappears. Instead of being divided into a number of "lessons," each of suitable length for one day's work of a practical class, the new volume is divided into "chapters" the length of which bears no proportion to the practical work of a class-meeting. In the other two volumes of the series, each lesson is commenced by a concise and definite description for the student of how to perform a number of experiments; and this description is followed by a few pages of theoretical teaching bearing on those experiments. In the present volume this arrangement is departed from, and the experiments are interpolated in a discursive fashion through the text.

An attempt is made to mark off by heavy type a portion of the book as an elementary course, but it is questionable whether this would not have been much better done by dividing the volume into an elementary and advanced course, as has been done by Prof. Halliburton in the "Essentials of Chemical Physiology." Again, some of the experiments described in this elementary portion are quite beyond the reach of the junior student—for example, the maximum work performed during a muscular twitch; while other simple and important experiments, such as the effect of temperature on muscular contraction, are excluded from this part.

The book commences with a description of various forms of galvanic cells and the chemical changes involved in their action. Such a description is scarcely necessary, for the student is supposed to be already familiar with the commoner forms of galvanic cell before commencing practical work in physiology; but, if inserted, it would have been much better to have described the action of the cells correctly. For example, the student who has just attended a junior course of instruction in a physical laboratory will be somewhat disturbed in his notions of electrolysis by being told that when the Daniell's element is in action—

> "the chemical changes in the battery are, solution of zinc and formation of $ZnSO_4$ at the zinc plate, and decomposition of the $CuSO_4$, *by the hydrogen appearing at the copper plate* to form H_2SO_4 and metallic Cu, which latter is deposited on the copper surface."

Similarly, in the case of the Bunsen cell the student is informed that, "the H_2 appearing simultaneously at the carbon pole (?) is oxidised into H_2O by the nitric acid." It is surely a new discovery that hydrogen appears at the negative plate in these elements, and one well calculated to upset all present electrolytic hypotheses.

The induction coil and its action are next considered, and here again some mistakes occur.

> "The E.M.F. of the induced current depends upon several factors: (1) It is directly proportional to the intensity of the current change in the first wire. (2) It is directly proportional to the rate of change of the inducing current."

It is difficult to see any difference between (1) and (2); there is probably a misprint somewhere, but this is precisely the kind of blunder most calculated to waste the time and temper of a student who is not strong in physics. In describing the theory of the extra currents of make and break it is stated that—

> "as the duration of this induced current (the extra current at make) is very short its effect is soon exhausted, but not before it has produced the result that more time is required for the current to reach its full strength than would have been the case if the wire had been perfectly straight."

Now the extra current at make lasts just as long as there is any variation of the primary current, and therefore as long as there is any induced current in the secondary coil, and its effect is no sooner over than any of the other effects involved.

A further error in connection with the same subject is worth noting, since it is not peculiar to this volume, but occurs in other text-books of physiology.

> "On breaking the circuit the circuit of the primary is broken, so that no induction currents can be set up in the primary."
>
> "The fall in potential is therefore instantaneous."

Now the fall in potential at break is *not* instantaneous, otherwise the E.M.F. of the induced current in the secondary circuit would be infinitely great. The primary circuit cannot by any means be instantly broken, and there *is* an induced extra current in the primary at break. Only in the circuit during break there is a high resistance in the spark gap, and both the extra current and the primary current are rapidly diminished by this rapidly increasing resistance.

The more purely physiological part of the book is fairly well written, and contains descriptions and figures of new and sometimes ingenious adaptations of simple apparatus for experimental work. Some of these artifices for making simple apparatus are certain to become extensively used, and it is here that the book will probably render most assistance to teachers of physiology. The book is also copiously illustrated, and contains a large number of reproductions of experimental tracings. Many of these it is impossible for the student to imitate for himself, but they will doubtless form valuable aids in assisting him to recollect the results of class demonstrations.

OUR BOOK SHELF.

L. Rütimeyer. Gesammelte Kleine Schriften allgemeinen Inhalts aus dem Gebiete der Naturwissenschaft. Nebst einer autobiographischen Skizze. Edited by H. G. Stehlin. 2 vols. 8vo. Pp. iv + 400 and 455. With a portrait and woodcuts. (Basel: Georg et C^{ie}, 1898.)

IN these two well-printed and handy volumes we have the more important of the contributions made to science by the late Prof. Rütimeyer, which could be reproduced without costly illustrations. By the kindly care of Leopold Rütimeyer and H. G. Stehlin, we have these as an "In Memoriam" tribute, the crowning stone of which is the very interesting series of notes by Prof. Rütimeyer himself of the chief incidents of his life. In a work of this nature, there is left but little room for criticism, and we will serve the reader's purpose best by a brief notice of the contents of the volumes. In the stray memories of his scientific life we learn that, born in February 1825, his early days were spent in the country; his life was in the open air, wandering over field and meadow, in woods, and up the hill-tops. Educated at home, he records his happiness at having escaped the mischiefs and sorrows of a public school. When sixteen years old, falling under the influence of Bernhardt Studer, his studies took the direction of the natural sciences, and his future career was marked out. In these "Memories" many are the interesting facts recorded in a busy life. As an author he began with a "Memoir on the Nummulitic Region of the Bernese Alps," which was published in 1848, and we have on record a long list, published from year to year, with but few exceptions, until 1895, when in June he put his initials to the "Memories," passing out of the world, though not beyond memory, on the 25th of the following November. Ever fond of nature, his latter years were rendered happier by winter sojourns in the sunny south of Europe.

The memoirs in the first volume are chiefly of a zoological character. We find an essay on the form and history of the vertebrate skeleton; on the historic method in palæontology; on the origin of our animal kingdom; on the limits of the animal kingdom—a critical notice on Darwin's writings; on the alterations in the animal life in Switzerland, since the appearance of man; on the evolution of organic beings. Most of these memoirs were at one time of interest, but while they were, as we think, worth gathering into a volume, it must be confessed that the greater part of their novelty has gone.

The second volume contains a long essay, "Vom Meer bis nach den Alpen," being a sketch of the structure, form and colour of the country met with in a section between England and Sicily; also a paper on the people of the Alps; a glance at the history of glacier studies in Switzerland; a very brightly written sketch of Brittany and its people. Obituary notices of Louis Agassiz, Charles Darwin, Peter Merian, and Bernhardt Studer, bring this volume to an end. There is in an appendix a list of all Rütimeyer's writings, arranged in chronological order.

Recherches expérimentales sur quelques Actinomètres Électro-chimiques. By H. Rigollot, Docteur ès Sciences, Chef des travaux de Physique a l'Université de Lyon. Pp. vi + 138. (Paris: Masson et C^{ie}, 1897.)

IN this work M. Rigollot has collected together, in a convenient form, his researches on photo-electric cells. Two metallic plates being immersed in an electrolyte, and the one exposed to light whilst the other is protected from it, a difference of potential is established between them. The author gives the large amount of valuable information, which he has accumulated in his study of this phenomenon, in the form of experimental results;

we cannot but regret the absence of any attempt to formulate a theory of them. The work is divided into three parts; in the first the effects of white light are studied, in the second the different parts of the spectrum are taken separately, and the third contains experiments on the increase of sensibility due to colouring matters. Plates of copper coated thinly with oxide, sulphide, fluoride, bromide and iodide, of tin coated with oxide and sulphide, and of silver coated with sulphide, are examined in solutions of some thirteen different salts.

The electromotive force developed depends on many circumstances, such as the thickness and nature of the coating, the concentration and nature of the electrolyte and the temperature, so that it is difficult to prepare two identical cells. The electromotive force of a given cell is, however, proportional to the intensity of the light when this is not too large. All the elements had a maximum sensibility in some part of the spectrum, the position of the maximum depending on the nature of the coating on the plates, but, for a given instrument, being independent of the nature of the electrolyte. With dyed plates the position of the maximum was independent of the compound of copper employed, but was determined by the nature of the dye, and was always found at a wave-length greater than that for which the colouring matter had a maximum absorption. The sensibility is largely increased by the employment of colouring matters. The actinometers may be employed for photometric purposes, since it is possible to prepare one with a maximum sensibility for almost any wave-length. Since the development of the electromotive force is accurately synchronous with the action of the light, they may also be used as radiophones.

Neudrucke von Schriften und Karten über Meteorologie und Erdmagnetismus. Edited by Prof. Dr. G. Hellmann. No. 10, Rara Magnetica, 1269-1599; No. 11, Ueber Luftelektricität, 1746-1753. (Berlin: A. Asher and Co, 1898.)

DR. HELLMANN is so well known by his laborious researches in matters relating to the history of early scientific documents and instruments, and by the very valuable bibliographical knowledge which he brings to bear upon the various publications of this nature, that it is unnecessary to say more than that the present volumes exhibit the same painstaking labour as those which have preceded them. The first contains fac-simile copies of some of the earliest papers on terrestrial magnetism and the mariner's compass; each document is very scarce, and only accessible with difficulty, and must be considered as a literary rarity. Among them is a letter from Pierre de Maricourt, dated August 12, 1269, which is the earliest known treatise on magnetism in Europe. The principal point in the paper is the distinction of the two poles of the magnet, and of their opposite attraction. A paper by F. Falero (Sevilla, 1535) contains the first published instructions for determining the magnetic declination, although its existence was discovered by Columbus in 1492. A letter by G. Hartmann, dated March 4, 1544, gives an account of his discovery of the magnetic dip and the first determination of the declination on the mainland. This document was buried in the archives at Königsberg until 1831, so that the discovery of the magnetic dip is generally attributed to R. Norman, who determined it for London in 1576. In a letter from G. Mercator to the Bishop of Arras, which was discovered during the present century in the library at Göttingen, the first mention is made of the earth possessing a magnetic pole. There are various other papers which we cannot refer to here, all of which are of great interest and value in throwing light upon the earliest development of the subject. The second volume contains a reproduction of the first fundamental papers relating to atmospheric electricity. The electrical nature of thunderstorms was suspected early in the eighteenth century by Hauksbee and other Englishmen, but Prof. J. H. Winkler, of Leipzig, first clearly demonstrated the analogy between them and the electric spark in 1746; the experimental proof was proposed by B. Franklin in 1749, and first carried out, near Paris, by Dalibard on May 10, 1752.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Does a Phosphorescent South American Liana exist?

IN collecting the literature regarding phosphorescent plants, I chanced on an article, by Mr. C. F. Holder, on "Living Lamps," in No. 392, vol. lxvi. (January 1883) of *Harper's Magazine*. In this article, at page 191, it is said: "In South America, a vine known as the Cipo, when injured, seems to bleed streams of living fire. Large animals have been noticed standing among its crushed and broken tendrils, dripping with the gleaming fluid, and surrounded by a seeming network of fire."

Could any reader of NATURE confirm the existence of this Cipo with a phosphorescent sap? Cipo, I believe, is a name for liana, not for vines. If true, the existence of a phosphorescent sap in a superior plant would be of great physiological interest. But no mention of this or a similar case is to be found in the standard works on vegetable physiology. I fear the statement may have as much foundation as the assertion, made in the same article, that among the peasantry of Italy girls complete their gala toilet with diadems of fireflies. ITALO GIGLIOLI.

Portici, near Naples, February 18.

Insusceptibility of Insects to Poisons.

YOUR reviewer's observation that one insect's food is another insect's poison, is applicable to a single insect at different stages of development. The scarlet fungus, *Agaricus muscarius*, derived its name from use in an old-fashioned decoction for fly-papers; nevertheless, it is eaten freely by maggots. Other poisonous fungi, such as *A. aeruginosus*, *A. phalloides*, *Russula emetica*, &c., are evidently innoxious to maggots and slugs. With regard to the effect upon more highly organised animals, it may be noted that *Boletus luridus* is eaten by mice and rabbits, and that squirrels are very partial to several species of *Tricholoma* and *Boletus*. I have some doubt as to whether squirrels are not occasionally poisoned by eating fungi, but I have not noticed any suspicious mortality in the case of the rabbits or mice.

February 19. H. B. POTTER.

The Mandrake.

IN a foot-note to my letter under this heading (NATURE, vol. liv. p. 343, August 13, 1896), I quoted from a Chinese work the names of the nine plants reputed to assume frequently the human or animal figures; and I remarked thereon that most of the alleged figures in these plants were recognised in their subterraneous members. Lately, however, I have found this remark not quite correct, inasmuch as it concerns some of them, viz. mustard and turnip: the alleged figures in these two appear to have suggested themselves to the Chinese imagination by the deformities in their floral parts caused by some parasitic infestations. This is evident from the following passage that occurs in "Mung-ki-pih-tan," written by Chin Kwoh (1031-94 A.D.): "When such vegetables as the turnips and mustard are injured by draught, their inflorescences mostly form the blossoms resembling the lotus-flower, or like the dragon and serpent. These are of common occurrence, and anything but wonderful. Once in the period of Hi-ning (1068-77 A.D.), when Mr. Li Kih-chi was the governor of Jun-chau, all blossoms of the vegetables in his garden happened to have the form of the lotus-flower, each having one Buddha sitting in it. They were innumerable, and looked as if engraved, and well preserved the figures after desiccation. Some one used to ascribe this ominous event to the great zeal with which all members of Mr. Li's family devoted themselves to the worship of Buddha."

February 21. KUMAGUSU MINAKATA.

ANTARCTIC RESEARCH.

THE desirability of a well-equipped expedition for the study of the Antarctic regions has been so frequently set forth by men of science, and recorded in the columns of NATURE, that little can now be said on the subject without repetition. But if little that is new can be said, much remains to be done; and unless the unanimous and often repeated declarations of British scientific men culminate in action, the reputation of science in this country will suffer seriously. The large and enthusiastic meeting of the Royal Society on Thursday last, February 24, showed more emphatically than had before been possible how great is the importance attached to the renewal of Antarctic exploration by the leaders of all departments of natural science. The meeting is fully reported below; but the steps which have led to it, and the reasons why the goal has not sooner been attained, may be referred to here.

Sir Wyville Thomson, on the return of the *Challenger*, and of the Arctic expedition which followed it, came to the pessimistic conclusion that "we can only anticipate disasters multiplied a hundred-fold should the South Pole ever become a goal of rivalry among the nations" (NATURE, xv. p. 123); but much has been learnt as to methods of polar travel since 1876, and the fear of possible disaster was, we believe, never strong enough to check any British scientific expedition. Dr. Neumayer had several years previously very strongly urged the importance of Antarctic work on many grounds (NATURE, vii. p. 21), and to him, more than to any other, is the recent revival of interest due. As early as 1875 the question was seriously raised in Australia, though not pressed.

At the British Association meeting in 1885 Sir Erasmus Ommanney urged the advisability of renewing Antarctic exploration, and a Committee was appointed to consider the matter. As a result the Royal Society of Edinburgh and the Scottish Geographical Society appointed Committees to draw up reports in 1886, which were published as an appendix to a paper on Antarctic exploration, by Dr. John Murray, in the *Scottish Geographical Magazine*, vol. ii. p. 527. At the Birmingham meeting of the British Association in 1886, a Report was presented stating the importance of a Government expedition, and Captain Creak, R.N., read a paper giving forcible expression to the necessity of research in the Far South from the point of view of terrestrial magnetism. The Australasian Colonies became keenly interested, and the Legislature of Victoria actually voted 5000*l*. to assist in an expedition if the Imperial Government would also take part in it. The Manchester meeting of the British Association in 1887 again considered the question, and at Bath in 1888 Sir Erasmus Ommanney's Committee gave in a final report expressing regret that Her Majesty's Government had declined to support the Australian proposals; which they did on the ground that if successful a more expensive expedition would be called for. During the year 1891 an effort was made in Australia to initiate a joint Australian and Swedish expedition, but without result, and financial difficulties afterwards prevented the renewal of Australian offers. At the Fifth International Geographical Congress at Bern, and at the British Association at Cardiff, papers were read by Sir Erasmus Ommanney and Mr. Delmar Morgan on the advisability of getting up an expedition. In 1892 a new phase of the question was entered upon. Whaling expeditions to the seas south of the Falkland Islands were despatched from Dundee and from Norway. Thanks to the efforts of Mr. Leigh Smith and the support of the Royal Geographical Society, the *Balæna* and *Active*, of Dundee, were supplied with instruments, and their surgeons, Messrs. Bruce and Donald, were selected with a view to making scientific observations. Captain Larsen, of the Norwegian whaler *Jason*, also made good observations. They returned in 1893, and the results, although not very striking, were sufficient to show the necessity for finding out more, and the comparative ease with which steam vessels could navigate Antarctic waters. The British Association again appointed a Committee, which reported in 1894.

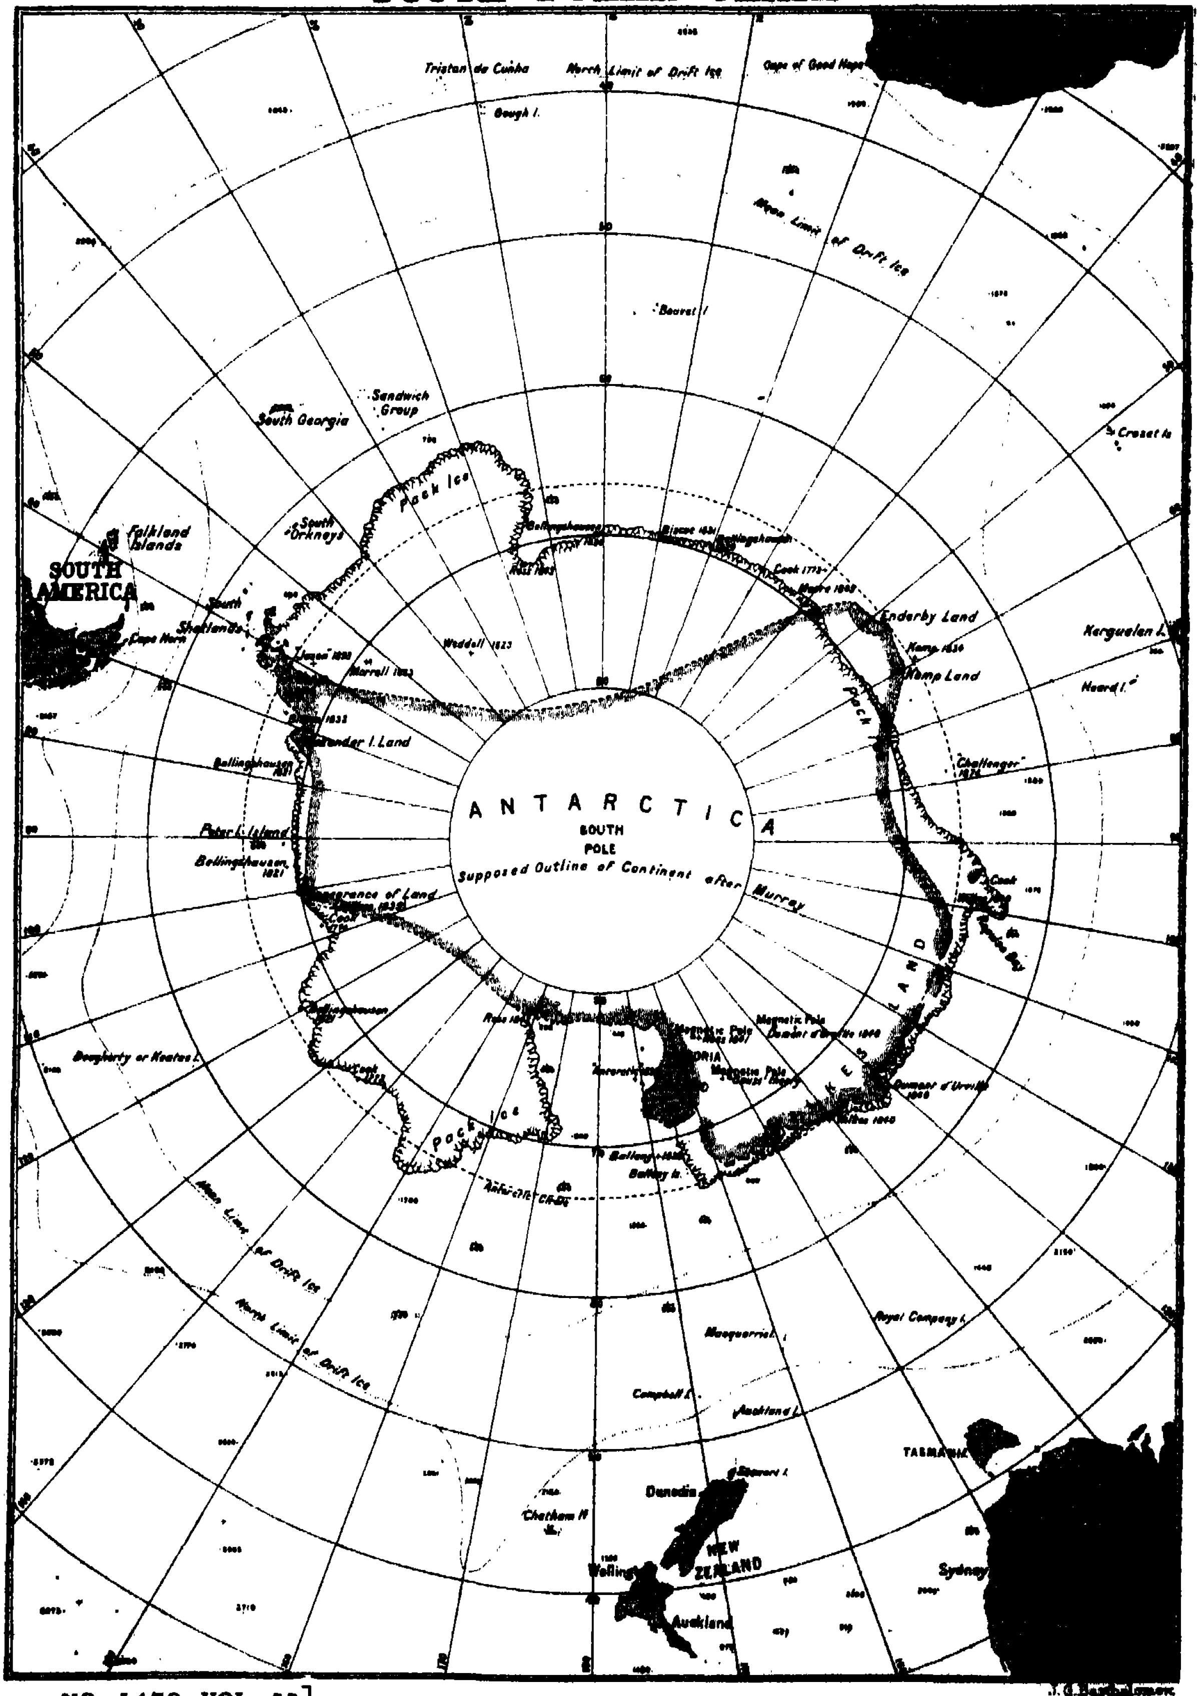
Meanwhile the Royal Geographical Society invited Dr. John Murray to bring the subject forward, which he did by an address at an evening meeting in November 1893. Interest in the question has been kept up ever since. Sir Clements Markham and other geographers have never ceased to urge by lectures, and articles in the press, the necessity of renewing exploration. In 1894 the representations of the Royal Geographical Society's Antarctic Committee induced the Royal Society to appoint a Committee which, after pronouncing in favour of a Government expedition, sought an interview with the authorities at the Admiralty. A recent article in the *Times* describes the result—"A deputation from the Royal Society waited upon the first Lord of the Admiralty to lay the matter before him; but another member of the Government intervened and informed the deputation that Sir James Ross, fifty years ago, had done all that was necessary for the exploration of the Antarctic."

In 1895 the Norwegian whaler *Antarctic* reached Cape Adare, where Kristensen and Borchgrevink landed. A conference of the greatest interest was held at the Sixth International Geographical Congress in London, and a resolution of enthusiastic approval carried. The British Association's Council reported, at their meeting in Ipswich, that after considering the question "the Council resolved to express their sympathy with and approval of the effort which is being made by the Royal Geographical Society." This was but cold encouragement, as the Association proposed to do nothing; but the promoters of Antarctic research were not at any time baffled by the ice-barriers of officialism, and efforts to compel attention to the scheme were renewed. The Royal Society appointed December 12, 1895, for a discussion on the scientific aspects of the case, to be introduced by Dr. John Murray, and arrangements were made in the same month for a deputation, representing the scientific societies of the United Kingdom, to wait on the First Lord of the Admiralty. He intimated that it would be inconvenient to receive it, on the ground of the small strength in officers of the British Navy making it impossible to spare the few required for an expedition. Circumstances led to the discussion being also postponed.

Throughout 1896 energetic efforts were made by various private individuals to get up commercial expeditions to the Antarctic regions, but without success. During the Jubilee rejoicings in 1897, the Royal Geographical Society seized the opportunity to hold a conference of Colonial Premiers and others, in the hope of reviving Australian offers of co-operation; and, encouraged by the result, the Society appealed once more to Government, not this time to the First Lord of the Admiralty, but to Lord Salisbury. It is understood that this representation is now under sympathetic consideration; and the great meeting at Burlington House has come at a singularly appropriate time. We may be sure that the unanimous voice of that meeting cannot be disregarded; and if an expedition is not now arranged, there must be a serious reason for it.

The demand for Antarctic research is no sudden impulse on the part of men of science; it originated independently in several quarters, and was not taken up by any of the great societies until it had been made quite clear that it was earnest and widely based. In Germany the agitation for an expedition has resulted in a nearly completed plan, and from Belgium the *Belgica* sailed last summer, and is, we hope, now at work in the southern ice. In July next Sir George Newnes will send out a private expedition under Mr. Borchgrevink, the work of which is sure to be full of interest. The Royal Geographical Society

SOUTH POLAR CHART



J. G. Bartholomew.

also could easily have arranged for a small expedition under competent leadership, had it not felt that preliminary work is not now so much wanted as substantial and sustained research, the expense of which would be too great for an individual or a society, though trifling to a nation. A large expedition is necessary, and a vast amount of anxiety and uncertainty as to the manner of working would be spared if it could sail under naval discipline, like the *Challenger*. There must be no mixture of commercial with scientific interests: when the conditions of the region are investigated, and its resources tested, private enterprise will not be slow to take practical advantage of useful discoveries. The incidental scraps of scientific value which commercial cruises have produced are undoubtedly useful to a certain degree; but scientific men on board vessels of that class have too frequently failed to work smoothly with the executive authorities. The exact relations to be observed between naval officers and civilian scientific staff can be determined in the light of past experience.

The object of Thursday's meeting was to elicit expert opinion as to the scientific advantages likely to be derived from adequate exploration of the South Polar region. In the absence through illness of Lord Lister, Sir John Evans presided, and the meeting-room of the Royal Society was crowded by a remarkable audience. In addition to the leading authorities in London on every branch of science, there were present the three men who have been nearest the two poles, Dr. Nansen and Lieut. Johansen from 86° N., and Sir Joseph Hooker from 78° S., the only survivor of Ross's expedition, and the last man alive who has seen Mount Erebus and the southern Ice Barrier. Dr. Neumayer, of the Deutsche Seewarte, came from Hamburg specially for this meeting, an example of international generosity to be the more esteemed because the German Antarctic expedition, which he has done so much to promote, is at last on the verge of taking definite shape. The Italian Ambassador also represented by his presence the friendly interest of a country which in 1880 made a courageous attempt, under Lieut. Bove, to take an active part in south polar work. Invitations to many of the younger scientific men engaged in departments of research bearing on the subject of the meeting had been sent out by the Society, and these were taken advantage of to the full. The interest of some who could not be present was conveyed by letter; a communication from the Duke of Argyll was read by the Secretary, dwelling on the value of the proposed expedition. Lord Kelvin had the evening before, while presiding at a lecture by Dr. Nansen in Glasgow, expressed his own views very strongly. Stating that the lecturer was leaving immediately after the lecture to attend the Royal Society meeting, he said, as reported in the *Glasgow Herald*: "The object of that meeting was to consider a proposal for an expedition to investigate the Antarctic polar regions, and Dr. Nansen was going to help the Society in its deliberations. If such an expedition were undertaken, and he hoped it would, it ought to receive the help of the Government. The British Government should make one of its primary objects the work of exploration, so that there should be nothing unknown of the whole ocean coast-line."

Dr. John Murray introduced the discussion by touching on all the scientific desiderata of the Antarctic regions; and after him nine speakers enforced and extended his arguments. Sir John Evans wisely decided that the discussion should be confined to the purely scientific aspect of the case, and the speakers closely followed his advice. The audience received the various addresses with applause such as is seldom heard in Burlington House. A good deal was made of the extent of our present knowledge, and an outsider might suppose that there was less diversity of opinion than really exists. The different estimates of the value of an Antarctic expedition to zoology, expressed by Dr. Sclater and Prof. D'Arcy Thompson, and the emphatic statement of the discrepancy between Ferrel's (or rather Dr. James Thomson's) theory of atmospheric circulation, and the indications of meteorological observations in the Far South, by Dr. Buchan, were stimulating and suggestive. How little we know of the Antarctic may be gauged from the map accompanying this article.

The meeting, the Chairman observed in closing it, was of unprecedented length, and a number of gentlemen who were prepared to take part had no opportunity to speak; while some of the speeches, especially that of Sir W. J. L. Wharton, in which he spoke of the popularity of such an expedition in the Navy, had to be cut very short. It would be worth while to consider whether some further opportunity might be given to bring before the scientific public the unheard arguments of last week.

The historical argument was not brought forward; but it is of importance in relation to the motive for exploration. At first the Antarctic question was the purely academic one of the possible existence of Antipodes, and was discussed by the ancient Greek geographers from analogy alone. On the revival of exploration in the fifteenth century, the existence of an Antarctic continent shutting in the Indian Ocean to the south, as supposed by Ptolemy, was a matter of much practical concern, for it affected the possibility of a sea-route to India. After the discovery that Africa could be rounded on the south, the appearance of the continent of America was looked on as a sign of the existence of a mass of Antarctic land. When Magellan penetrated his straits, and even after the rounding of Cape Horn, a vast Antarctic continent reaching to the tropics was a matter of common belief. Cook's first voyage of exploration detached New Zealand from this hypothetical continent; his second proved that any continent which might exist lay within the Antarctic circle. With this discovery the political motive for Antarctic exploration vanished. The only possible reason for adequate exploration was thenceforward scientific, and sixty-four years after Cook returned the ships of Sir James Clarke Ross set out on their great cruise. That was fifty-nine years ago. The intervals of sixty-four and fifty-nine years were both marked by the incidental work of other expeditions, such as the circumnavigations of Bellingshausen and Dumont d'Urville, and that of the *Challenger*. Commercial enterprise also sent out a number of daring sailors, the fleets of the Enderbys before Ross, and those of the Scottish and Norwegian whalers since. The commercial motive has proved insufficient in the south, potent as it was for many centuries in the north. The fact stands to-day that if the scientific motive fails to produce the result, the Antarctic regions will never be explored.

Putting the matter in its simplest form, civilised man must understand his dwelling-place; the key to many puzzles, the end of many controversies affecting the theory of the phenomena of the whole world, lies behind the vast Antarctic veil. It is the duty of the human race to lift that veil, whether there be much or little behind it, and the British people, as represented by the Government, ought to take the lead. We ought to take the lead because our territory in Australasia, Africa, and the Falkland Islands comes nearest to the unknown region; because our national welfare is more concerned than any other in the intelligent and safe navigation of the Southern Ocean; and because our Government, our Navy, and our scientific societies are richer and stronger now than they were in the days of Cook and of Ross, both absolutely and with reference to other nations. That other nations are preparing, or have prepared, to take part in wiping off this huge reproach on the enterprise and the self-respect of nineteenth century man should surely be an inducement to action rather than a deterrent. The value of simultaneous expeditions working in friendly rivalry is in such a case far greater than that of consecutive or isolated work.

HUGH ROBERT MILL.

ERNST CHRISTIAN JULIUS SCHERING.

ON November 2, 1897, as already announced in NATURE, Göttingen lost, at the age of sixty-four, its senior mathematical professor, Ernst Christian Julius Schering, best known as the editor of Gauss's works.

Prof. Schering's life presents one curious feature, rare in the German academic world. Göttingen was the only University with which as student, teacher, or professor he had any connection. The forty-five years of his life there go back to the days when Gauss, Wilhelm Weber and Dirichlet still lived and taught. Although the first of these was to exercise paramount mastery over Schering's future, we can trace the influence of each in his life and writings. Schering's published work deals entirely with subjects in which his celebrated teachers were pioneers—theory of numbers, non-Euclidian geometry, hydrodynamics, electricity and magnetism. As far as one can judge, Schering's personal predilections were for a strictly analytical treatment of pure mathematics; the force of circumstances, however, directed part of his energies to applied mathematics and practical physics. He is said to have shown great mathematical promise at school at Lueneborg and at the Polytechnikum at Hanover; so much so that he abandoned his intention of becoming an architect, and went up to the University in 1852. His studies were crowned with success, and he received prizes both for his Doctor's dissertation, "On the mathematical theory of electric currents," and for his Habilitationsschrift, "On the conformal representation of the ellipsoid on the plane."

In 1860 he became Professor, and was at first engaged in astronomical calculations under Prof. Klinkerfues. In 1863 he embarked on his life-work, the editing of Gauss's papers. Gauss left, besides a large quantity of published work, a mass of notes and of half-finished productions. The work of collecting the published papers, and of looking through, arranging and collecting the unpublished, fell to Schering. From 1863 to 1874 he edited six volumes of collected works, published by the Gesellschaft der Wissenschaft, of Göttingen. He subsequently edited the *Theoria Motus* for the owner of the copyright; this volume, though apparently uniform with the others, does not properly belong to the set, and, the copyright having now expired, the Gesellschaft propose to publish the *Theoria Motus*, together with some still unpublished writings, in a seventh volume of their edition.

It is difficult for any one who has not seen the documents to estimate the labour required to bring them into a form fit for publication. There still remains an enormous mass of unpublished matter, notes on scraps of paper and backs of envelopes, calculations without explanations, statements without proofs, and so on. Until a lingering illness rendered him unfit for much exertion, Schering went on working to bring order into this chaos; but he was unwilling to publish except in a perfected form. Since 1874 no volume had appeared, and, except Prof. Schur, no one had access to any of the original manuscripts.

There was consequently great curiosity about the MSS. when, on Prof. Schering's death, they were brought out and examined. A number of mathematicians have been enlisted by Prof. Klein, and it is hoped that at least the notes on planetary disturbances and the correspondence on non-Euclidian geometry will soon be published. Work that is too imperfect for publication will in future be always accessible at the University library.

Apart from those already mentioned, Schering published numerous papers, mostly to be found between 1870 and 1887, in the Göttingen *Nachrichten* and *Anzeiger* and the *Comptes rendus*. His lectures, which for some years he had done little more than announce, were usually on higher pure mathematics.

In 1868 he became director of the Gauss Magnetic Observatory. His work consisted partly in directing the studies of students in magnetism and kindred subjects, partly in conducting observations, &c. Generally he continued and extended the work as Gauss had planned it. Accounts of his observations, and of various improvements made by him in the instruments, will be found in papers by himself and his brother, Prof. Karl Schering, of Darmstadt.

W. H. AND G. CHISHOLM YOUNG.

NOTES.

ON Saturday last, at the Trocadero Restaurant, a dinner was given to Prof. T. McKenny Hughes by his old students, on the occasion of the twenty-fifth anniversary of his election to the Woodwardian Professorship of Geology at Cambridge. Sir Archibald Geikie presided, and covers were laid for old students and friends to the number of sixty-five. An illuminated address was presented to Prof. Hughes by Dr. R. D Roberts and Mr A. Strahan as the oldest and earliest of his Cambridge students in the company; and the healths of Prof. and Mrs. Hughes were proposed by Sir A. Geikie. In the course of his speech, Sir A. Geikie alluded to the great and continued growth and success of the Cambridge Geological School, which he characterised as second to none in the world. Prof. Hughes replied, and subsequently the President of the Geological Society (Mr. Whitaker), Sir Henry Howorth, M.P., Prof. James Stuart, M.P., and Dr. Hicks spoke and testified to the value of Prof. Hughes's professional work, and to the wide extent of his personal influence. In addition to those above mentioned, there were present Prof. Wiltshire, Mr. W. Hudleston, Prof. Etheridge, Dr. Henry Woodward, Prof. Lapworth, Prof. Watts, Prof. Ainsworth Davis, Messrs. Teall, Herries, Bauerman, Marr, Harker, Seward, Woods, Reed, Rudler, Kynaston, Mond, and several ladies, many of whom had studied under Prof. Hughes at Cambridge. Letters and telegrams of congratulation from leading Continental geologists were read by Sir A. Geikie. A magnificent silver loving-cup was presented to Prof. McKenny Hughes on Monday, February 28, by his past and present students at Cambridge as a permanent memento of his twenty-five years' work as Woodwardian Professor of Geology, and as a mark of their esteem and gratitude. The cup bore a suitable inscription in Latin, and the arms of the University and of Trinity and Clare Colleges; and an illuminated list of the subscribers was presented with it. Mr. Cowper Reed, Miss Blanche Smith, Dr. Roberts, Prof. Ainsworth Davis, and Rev. W. L. Carter made appropriate speeches, and Prof. Hughes replied.

THE Physico-Mathematical Society of Kazan has made its first award of the Lobachévski Prize to Prof. Sophus Lie, of the University of Leipzig, in consideration of the third volume of his work, "Theorie der Transformationsgruppen." The prize, which is of the value of 500 roubles, is to be adjudged every three years for work in geometry, preferably non-Euclidean geometry, and all works published in Russian, English, French, German, Italian, or Latin in the six years preceding the award are eligible. In Prof. Lie's treatise the theory of non-Euclidean geometry has been exhaustively re-stated and re-established in a profound investigation on the space-problem, based on the work of the late von Helmholtz.

IT is announced in the *Times* that the Local Government Board has given orders that the new form of vaccine mixed with glycerine, described in last week's NATURE (p. 391), is to be served out to all vaccination officers, following upon the recommendation of the Special Commission on Vaccination, which recently examined all the great vaccination departments of foreign Governments. This is to be undertaken at once, without regard to the vaccination legislation promised in the Queen's Speech, and will be completely independent of such a measure. Some delay has arisen in sending out the new lymph, owing to the want of a special laboratory for the cultivation of the matter; but this will not now be long delayed, as soon as the Local Government Medical Board is granted funds to purchase or secure a laboratory.

M. DE FONVIELLE informs us that the President of the International Commission for the exploration of the high atmosphere has issued a circular notifying that a conference will be held at Strassburg on March 28, to discuss the results obtained up to this time by the ascent of free balloons to high altitudes, and determining the measures which are to be taken to collect registered observations. The German kite-balloons and American meteorological kites will also be subject for discussion. Invitations have been sent to a number of men of science who are working in similar fields of inquiry. The remarks and discussions will be carried on in three languages—English, French, and German.

ON Saturday last, February 26, the Council of the Society of Arts attended at Marlborough House, when the Prince of Wales, President of the Society, presented the Albert Medal to Mr. G. J. Symons, F.R.S., "for the services he has rendered to the United Kingdom by affording to engineers engaged in the water supply and the sewage of towns a trustworthy basis for their work, by establishing and carrying on during nearly forty years systematic observations (now at over 3000 stations) of the rainfall of the British Isles, and by recording, tabulating, and graphically indicating the results of these observations in the annual volumes published by himself."

THE lists of prize competitions for 1898 and 1899 have just reached us from the Belgian Academy. The international competitions consist in the answering of six questions, for each of which a prize of 600 francs is offered. These questions are the following: (1) Describe the researches already made on critical phenomena in physical science, and complete them by new researches. (2) Expound and criticise the various theories of the constitution of solutions, and supplement them by new researches, especially with regard to the existence of hydrates in aqueous solution. (3) Make some important contribution to the theory of correspondences (*Verwandtschaften*) between two spaces. (4) Original research on digestion in carnivorous plants. (5) Original research on the structure and development of a Platode, with the object of determining whether there are any phylogenic relations between Platyhelms and Enterocœlians. (6) Do the Schizophytes possess a nucleus? If so, what is its structure and its mode of division? In addition, a prize of 800 francs is offered for a solution of the problem of determining the influence exercised by the nitryl radicle NO_2 in aliphatic compounds on the characteristics or functions appertaining to alcohol, haloid ether, oxy-ether, &c. All papers must be written in French or Flemish, and must be sent to M. le Secrétaire perpetuel, au Palais des Académies, Bruxelles, before August 1, 1898. They must bear a motto (not a pseudonym), and must be accompanied by a sealed envelope bearing the same motto outside, and the competitor's name and address inside. Special correctness is required in the matter of quotations. The conditions for 1899 are similar. The questions relate to the thermal conductivity of liquids and solutions, to straight-line geometry, to the variation of latitude, to albuminoid substances in nutrition, to the Apterygota, and to the Upper Eocene period.

THE Rome correspondent of the *Daily Mail* announces that King Humbert has given his permission to his young nephew, the Duke of the Abruzzi, to undertake an expedition in the Arctic regions. The Prince intends to visit Greenland and Lapland, and to study the sea currents and the geology of the locality. He will be accompanied by an aide-de-camp, by Drs. Gonella and Defilippi, who were his companions in the expedition to Alaska, and by a few young naval officers. According to a Reuter telegram from Christiania, the Duke will leave next summer for Spitsbergen in order to explore the country, but the expedition will not start until 1899, and its first objective will be Franz Josef Land. Should the conditions of the ice be favourable, depôts will be established, and an attempt will be made to reach the Pole by means of sledges and dogs. In the event of this proving impracticable, the expedition will confine itself to an exploration of Franz Josef Land. On the advice of Captain Sverdrup, the Duke will ask the Danish Government for a supply of dogs from Greenland, as these are considered to be the best.

THE brilliant lantern slides exhibited by Dr. Isaac Roberts at the Royal Societies' Club on Wednesday, February 23, in illustration of his lecture on "Recent Intelligence from Regions in the Stellar Universe," constituted a striking testimony to his achievements in astronomical photography. The nebulæ and clusters of stars which Dr. Roberts has now photographed number about five hundred, and a list of them, as they are taken each year, is published in his annual Observatory Report in the *Monthly Notices* of the Royal Astronomical Society. It is not too much to say that these photographs contain a mine of new astronomical information which has not yet been worked, and the value of which will increase with years. The pictures represent celestial species awaiting the mind of a Darwin to coordinate them; for they show stellar systems in the various stages of growth from the embryonic nebula to the finished star. Dr. Roberts has himself endeavoured to discover the scheme of stellar evolution as revealed by his photographs, and he placed the results before his audience last week. His method of doing this was soundly scientific. To begin with, he showed a number of photographs of star regions in which the stars could be seen grouped into semicircles, segments, portions of ellipses, and lines of various degrees of curvature. Some of these groups were composed of bright stars of nearly equal magnitude; some of faint stars, also of nearly equal magnitude; while the distances between the stars in the various groups were remarkably regular. Passing from these characteristics of stellar arrangement to photographs of spiral nebulæ, Dr. Roberts pointed out that the nebulous matter in the spirals was broken up into star-like loci, which in the regularity of their distribution resembled the curves and combinations of stars exhibited by photographs upon which no trace of nebulosity was visible. It thus seemed that the curvilinear grouping of stars of nearly equal magnitude gave evidence that the stars had been evolved out of some attenuated material in space by the action of vortical motions and by gravitation. Exactly how the vortical motions were caused, or what has brought about the distributions of nebulosity in the spiral nebulæ, cannot be answered; but the marvellous pictures exhibited by Dr. Roberts establish the reality of the grouping, and furnish students of celestial mechanics with rich food for contemplation.

THE Bishop of London, one of its Vice-Presidents, has consented to preside at the annual general meeting of Governors of the Dental Hospital of London, to be held at the Hospital, Leicester Square, on Thursday, March 17, at 5.30 p.m.

A CORRESPONDENT writes to inform us, with respect to the Lincolnshire Naturalists' Union, that the papers written by members of that association are published in the *Naturalist*, which is issued under the auspices of the Yorkshire Naturalists' Union. While desirous in every way to further the interests of local societies, the demands upon our space render it impossible for us to enter into local controversies, and we must decline to notice any further communications relating to this division among the naturalists of Lincolnshire.

THE following are the arrangements for lectures during March at the Imperial Institute. These lectures will be open free to the public, without tickets, seats being reserved for Fellows of the Imperial Institute and persons introduced by them. Monday, March 7, at 8.30, "The Mineral and other Resources of Newfoundland," by Mr. J. H. Collins; Wednesday, March 9, at 3, "A Demonstration with the Cinematograph of 'Harvesting in Manitoba in 1897,'" by Mr. J. S. Freer; Thursday, March 10, at 8.30, "Colonisation in Canada," by the Marquis Bouthillier-Chavigny; Monday, March 14, at 8.30, "The Alps of New Zealand," by Mr. E. A. Fitzgerald; Monday, March 21, at 8.30, "Siam—Present and Future," by Mr. Frederick W. Verney; Monday, March 28, at 8.30, "On a proposed Railway Connection between India and Ceylon," by Mr. John Ferguson.

FROM a preliminary note in the *Atti dei Lincei*, we learn that Dr. B. Longo, by studying the embryology of the *Calycanthaceæ*, has discovered in their ovules certain characteristics forming a new link between this order of plants and the *Rosaceæ*.

WE are glad to see that an attempt is being made to increase the usefulness of the collections of abstracts which, under the editorship of Mr. J. Swinburne, have for several years constituted the second half of the *Proceedings* of the Physical Society of London. With the title "Science Abstracts, Physics and Electrical Engineering," these records of current research have now, for the first time, appeared in separate form, and the Institution of Electrical Engineers has now co-operated with the Physical Society in their publication. Mr. Swinburne still holds the post of editor, and Mr. W. R. Cooper has been appointed sub-editor. The change is calculated both to extend the circulation and enlarge the scope of these abstracts by introducing matter of a practical nature without detracting from the value of the notices of the more theoretical papers. The numbers may be obtained by non-members from the publishers, Messrs. Taylor and Francis.

IN a communication to the *Philosophical Magazine* for February, on the failure of german-silver and platinoid wires used for resistance coils in tropical climates, Mr. Rollo Appleyard remarks:—"Can metallurgists tell us the difference in constitution and structure between a german-silver wire that decays in four weeks and another that, under similar circumstances, never fails? Or, what is even more important, can they make us platinoid that shall never *fail*? If they cannot, it becomes necessary to surrender these cheaper and better electrical materials, and fall back upon the more expensive alloys, beginning at platinum-silver. If sufficient time and means were at the disposal of metallurgists, they might discover the secret of permanence in alloys. Germany, with the advantages of a National Laboratory, has already attacked the question, and "manganin" is the result. Its adoption there as a satisfactory alloy is directly due to work done at the Reichsanstalt. But it has yet to be proved that manganin will endure the conditions imposed by the tropics. Moreover, the doubt arises as to whether it is desirable to obtain from abroad material that ought to be produced in our own country. British cable manufacturers are already importing thousands of tons of sheathing wire from Germany; and it seems probable that, for the want of a National Laboratory, instrument-makers will now get their resistance-wire from that same adventurous foreign source."

THE Report of the Meteorological Council for the year ending March 31, 1897, has recently been presented to Parliament. The Office continues to collect data relating to the meteorology of the ocean, and supplies complete outfits of meteorological instruments to officers of merchant ships who are willing to make observations. Her Majesty's ships are also supplied with instruments, and valuable observations are received from officers of the Royal Navy. We have previously noticed the monthly current charts which have been published for several oceans. A work on the meteorology of the Southern Ocean, between the Cape of Good Hope and New Zealand, is in course of preparation; and as no charts for this area have been previously published by the Office, the work will probably be of much value. The results of the weather forecasts continue to show a considerable amount of success; for those published in the morning newspapers a complete or partial success of 81 per cent. is claimed for the year in question, while for the special forecasts issued during the hay-harvest, the figures show that 88 per cent. were useful. A still greater success is claimed for the warnings of storms, no less than 91·5 per cent. being justified. For the study of the climatology of the British Isles, the Office continues to subsidise, and to maintain an intimate relationship with, a small number of observatories of the highest class, and to supplement this information by observations from a large number of voluntary stations. The principal miscellaneous investigations during the year refer to anemometer experiments, earth temperatures, and the recently published rainfall statistics for the British Islands.

UNDER the name of "alinit" a new manure suitable for all kinds of grain has been recently introduced to the scientific and agricultural worlds by that enterprising firm of colour manufacturers, Friedrich Bayer and Co., whose name is already so indissolubly associated with nitragin, and the production of diphtheria anti-toxins. The discoverer of this mysterious material is a certain Herr Caron, of Ellenbach; and alinit in its present form is the outcome of four years' laborious experimental investigations on the bacterial flora of different soils, resulting in the isolation of a particular bacillus, upon the presence of which would appear to depend to an important extent the fertility of certain soils. Caron has already obtained striking results on an experimental scale with crops from soil treated with pure cultures of this bacillus—*Ellenbachensis alpha*, as he has called it. Alinit is to be had commercially from the above firm, and is sent out as a creamy-yellow powder, of which the nitrogenous constituents have been ascertained to be 2·5 per cent. Its closer investigation has been made the subject of memoirs by Stoklasa, of Prague, and also Messrs. Stutzer and Hartleb. The bacillus is contained in this powder in the form of spores, and on cultivation is found to belong to the well-known aërobic group of bacteria known as the hay bacilli, resembling very closely the bacillus mycoides so frequently found in soil, and the bacillus *Megatherium*. It appears to grow easily upon all the usual culture media. Before its precise place amongst bacterial fertilisers can be determined, many more elaborate and carefully-conducted experiments must be carried out.

PROF. ARNALDO FAUSTINI contributes to the *Bollettino* of the Italian Geographical Society, which, by the way, appears in a new ornamental cover, a note on the "Appearances of Land" recorded by various voyagers in the Antarctic regions. The paper gives point to some of the strongest arguments for Antarctic research, and summarises the topographical uncertainties which future expeditions must set themselves to clear up.

AT the meeting of the Vienna Academy of Sciences, on December 16 last, letters were read from Dr. Steindachner, the Director of the *Pola* Expedition in the Red Sea. Writing at the end of November, Dr. Steindachner reports that deep-sea work was at an end, but that observations along the coast and amongst the islands were being continued as the very unfavourable weather permitted. Valuable collections were made on the Dahalak and Nakra Khor islands, specially in connection with the coral formations and the shallow-water fishes; and the extinct volcanoes and the lava-sheets of Peacock Hill Bay were examined. The *Pola* reached Assab on November 30, and Mocha on December 14, 1897.

M. LE COMTE P. DE BARTHELEMY publishes a letter in the *Comptes rendus* of the Paris Geographical Society, on the possible lines of communication between Luang-Prabang and the coast, and on the navigability of the Mekong. It would seem that little or nothing can be made of the Tran-Nunh plains as long as they remain in the hands of the present degenerate population; although something might be possible if the Meo population of the mountainous districts took their place. The only part of the Mekong really adapted to navigation is the stretch of 650 kilometres between Vien-Tiane and Savannakhek. The future of Luang-Prabang evidently depends on the speedy realisation of one or more of the numerous railway schemes proposed.

MR. PORTER has just published the tenth part of Messrs. Sclater and Thomas's illustrated "Book of Antelopes." Two more parts, already in a forward state, will finish the account of the Gazelles and allied forms, and bring the third volume to a close. The fourth and concluding volume will be devoted to the Oryxes and Strepsiceres. Altogether the work will contain one hundred coloured plates, about seventy of which were originally prepared under the superintendence of the late Sir Victor Brooke, many years ago, for a somewhat similar work which he had planned, but did not live to accomplish.

IN referring to the election of three new members of the Athenæum Club, in the first note last week, the designation of the Club was inadvertently omitted.

DR. G. LINDSAY JOHNSON writes calling attention to an obvious misprint in the fortieth stereotyped edition of Vega's Logarithmic Tables. The logarithmic sine of 0° 6′, printed as 9·2418771, should be 7·2418771.

PROF. CHARLES FABRE, of the University of Toulouse, has just completed the second supplement to his well-known treatise on Photography. The new volume deals with the progress made in all branches of the subject during the years 1893 to 1896.

THE additions to the Zoological Society's Gardens during the past week include three Black-backed Jackals (*Canis mesomelas*) from South Africa, presented by Mr. J. E. Matcham; a Black-backed Jackal (*Canis mesomelas*) from South Africa, presented by Captain Travers; two Black Spider-Monkeys (*Ateles ater*) from Eastern Peru, a Downy Owl (*Pulsatrix torquata*) from Pará, twelve White's Tree Frogs (*Hyla cærulea*) from Australia, deposited; a Temminck's Tragopan (*Ceriornis temmincki*) from China, a Bearded Lizard (*Amphibolurus barbatus*) from Australia, purchased.

OUR ASTRONOMICAL COLUMN.

ECLIPSE NEGATIVES.—In order to minimise the risk in returning the eclipse negatives to England from the Eclipse Station at Viziadrug, they were divided into three batches, a complete set being made up in each batch by positives from the other negatives. Two of these sets have already arrived safely in England, and they testify to the clearness of the atmosphere during totality. The smallness of the prominences is very noticeable, both in hydrogen and K (calcium) radiations, a fact which was observed at South Kensington in H_a light on the day of the eclipse. Another conspicuous feature is the intense brightness of some of the coronal streamers at their base. The negatives of the corona also verify the reports from the visual observations, which stated that the general form was like those of 1886 and 1896. The resemblance to the latter is very striking, especially when we remember that it was the north point of the axis which was presented to us at that eclipse; whilst in the last eclipse in January, the south point of the axis is inclined towards us.

CINEMATOGRAPH IN ASTRONOMY.—We have already learnt that the cinematograph was employed with success during the recent solar eclipse, but M. Camille Flammarion has turned it to the further use of exhibiting to a large audience the various celestial movements. He has photographed the heavens at different times from sunset to sunrise with a wide-angled lens in the cinematograph, and as the whole movements during a single night are projected on the screen, and passed through in a few minutes, no very rapid rate of exposing the photographs is required. For showing sunset at one horizon, followed by the movement of the stars and sunrise at the other horizon, and also the movement of the moon amongst the stars, this method has been employed with great success. He proposes in addition to this to photograph the sun-spots, and thus exhibit by their movement the rotation of the sun. For the earth he has constructed a large model, and photographed it with a cinematograph when rotating and illuminated by light arranged so as to represent the sun; this was exhibited at the last meeting of the French Astronomical Society, and was greatly admired.

A PROBABLE NEW STAR.—In *Astr. Nach.*, No. 3476, it is pointed out that the probable new star announced by Espin, and not in the B.D., is, however, in the small edition as an addendum, + 32°·1526*a*; 8·0 mag., 7h. 12m. 15·6s., + 32° 18′·4 L. This is the same star as recorded by the Rev. T. E. Espin, so in all probability it is another observation of a variable star. An examination of its spectrum, made at South Kensington, at once showed that the star had not a spectrum peculiar to temporary stars, and hence was probably only an omission from the star charts.

ELECTROLYTIC REFLECTORS.—In a paper read before the Institution of Electrical Engineers, and reproduced in *Industries and Iron* for February 18, Mr. Sherard Cowper-Coles describes a method by which a metallic reflector can be made by an electrolytic process. The method is intended, in the first place, for the manufacture of metallic mirrors for use as projectors in search lights, and also to overcome the difficulty that has been experienced in producing a true metallic reflector that will not readily tarnish when exposed to the heat of an arc light; but the same method is also applicable for the production of mirrors for astronomical purposes. The process is, of course, a copying one, and consists in taking a concave surface from a convex mould, so figured as to give the correct curvature to the copy taken from it. In the words of the author, "a glass mould is prepared, the convex side of which is accurately shaped and polished to form a true reflecting surface. On the prepared surface is deposited a coating of metallic silver, which is thrown down chemically on the glass, and then polished so as to ensure the copper backing being adherent to the silver. The mould thus prepared is placed in a suitable ring and frame, and immersed in an electrolyte of copper sulphate, the mould being rotated in a horizontal position. The copper adheres firmly to the silver, and together they form the reflector, which is subsequently separated from the glass mould by placing the whole in cold or lukewarm water, and then gradually raising the temperature of the water to 120° F., when the metal reflector will leave the glass mould, due to the unequal expansion of the two." The concave surface of the reflector thus obtained has a brilliant polish, and requires no further treatment to answer all the purposes of a reflector; but for uses where tarnishing would soon take place, it is further immersed in a bath of palladium ammonium chloride, and a coating of palladium deposited on the concave side; this metal does not tarnish readily, and resists heat to a wonderful degree.

This new method of making mirrors electrolytically would seem to have a promising future before it, for great pains could be taken in making the mould, from which any number of copies could be taken without the usual laborious process of grinding and figuring each individual mirror, and yet each one would have a correct reflecting surface.

SCIENTIFIC ADVANTAGES OF AN ANTARCTIC EXPEDITION.[1]

DR. MURRAY'S ADDRESS.

FROM a scientific point of view the advantages to be derived from a well-equipped and well-directed expedition to the Antarctic would, at the present time, be manifold. Every department of natural knowledge would be enriched by systematic observations as to the order in which phenomena coexist and follow each other, in regions of the earth's surface about which we know very little or are wholly ignorant. It is one of the great objects of science to collect observations of the kind here indicated, and it may be safely said that without them we can never arrive at a right understanding of the phenomena by which we are surrounded, even in the habitable parts of the globe.

Before considering the various orders of phenomena, concerning which fuller information is urgently desired, it may be well to point out a fundamental topographical difference between the Arctic and Antarctic. In the northern hemisphere there is a polar sea almost completely surrounded by continental land, and continental conditions for the most part prevail. In the southern hemisphere, on the other hand, there is almost certainly a continent at the South Pole, which is completely surrounded by the ocean, and, in those latitudes, the most simple and extended oceanic conditions on the surface of the globe are encountered.

The Atmosphere.

One of the most remarkable features in the meteorology of the globe is the low atmospheric pressure at all seasons in the southern hemisphere south of latitude 45° S., with the accompanying strong westerly and north-westerly winds, large rain and snow fall, all round the South Polar regions. The mean pressure seems to be less than 29 inches, which is much lower than in similar latitudes in the northern hemisphere. Some meteorologists hold that this vast cyclonic system and low-pressure area continues south as far as the pole, the more southerly parts being traversed by secondary cyclones. There are, however, many indications that the extreme South Polar area is occupied by a vast anticyclone, out of which winds blow towards the girdle of low pressure outside the ice-bound region. In support of this view it is pointed out that Ross's barometric observations indicate a gradual rise in the pressure south of the latitude of 75° S., and all Antarctic voyagers agree that when near the ice the majority of the winds are from the south and south-east, and bring clear weather with fall of temperature, while northerly winds bring thick fogs with rise of temperature.

All our knowledge of the meteorological conditions of the Antarctic is limited to a few observations during the midsummer months, and these indicate that the temperature of the snow-covered Antarctic continent is even at that time much lower than that of the surrounding sea. The anticyclonic area at the South Pole appears therefore to be permanent, and when in winter the sea-ice is for the most part continuous and extends far to the north, the anticyclonic area has most probably a much wider extension than in summer. This is indicated by the south-easterly winds, which at times blow towards the southern point of the American continent in June and July.

All observations in high southern latitudes indicate an extremely low summer temperature. In winter we have no direct observations. The mean of Ross's air temperatures south of latitude 63° S. was 28·74° F., which is about the freezing-point of sea-water, and his maximum temperature was 43·5° F. Both Wilkes and D'Urville observed pools of fresh water on several icebergs, and, when sailing along the ice barrier, Ross saw "gigantic icicles depending from every projecting point of its perpendicular cliffs" (Ross, "Antarctic Voyage," vol. i. p. 237), so it is probable that extensive melting sometimes takes place.

In the latitude of the Antarctic circle the air is frequently at or near the point of saturation, and precipitation takes place in the form of rain, sleet, snow, or hail. Most of the observations near the ice-covered land show, however, a much drier atmosphere, and in all probability precipitation over the Antarctic continent takes place in the form of fine snow crystals, such as is recorded in the interior of Greenland.

There would appear, then, to be good reasons for believing that the region of the South Pole is covered by what may be regarded practically as a great permanent anticyclone, with a much wider extension in winter than in summer. It is most likely that the prevailing winds blow out from the pole all the year round towards the surrounding sea, as in the case of Greenland; but, unlike Greenland, this area is probably seldom traversed by cyclonic disturbances.

But what has been stated only shows how little real knowledge we possess concerning the atmospheric conditions of high southern latitudes. It is certain, however, that even two years' systematic observations within these regions would be of the utmost value for the future of meteorological science.

Antarctic Ice.

From many points of view it would be important to learn something about the condition and distribution of Antarctic sea-ice during the winter months, and especially about the position and movements of the huge table-shaped icebergs at this and other seasons of the year. These flat-topped icebergs, with a thickness of 1200 or 1500 feet, with their stratification and their perpendicular cliffs, which rise 150 or 200 feet above and sink 1100 or 1400 feet below the level of the sea, form the most striking peculiarity of the Antarctic Ocean. Their form and structure seem clearly to indicate that they were formed on an extended land surface, and have been pushed out over low-lying coasts into the sea.

Ross sailed for 300 miles along the face of a great ice-barrier from 150 to 200 feet in height, off which he obtained depths of 1800 and 2400 feet. This was evidently the sea-front of a great creeping glacier or ice-cap just then in the condition to give birth to the table-shaped icebergs, miles in length, which have been described by every Antarctic voyager.

All Antarctic land is not, however, surrounded by such inaccessible cliffs of ice, for along the seaward faces of the great mountain ranges of Victoria Land the ice and snow which descend to the sea apparently form cliffs not higher than 10 to 20 feet, and in 1895 Kristensen and Borchgrevink landed on a pebbly beach, occupied by a penguin rookery, at Cape Adare without encountering any land-ice descending to the sea. Where a penguin rookery is situated, we may be quite sure that there is occasionally open water for a considerable portion of the year, and that consequently landing might be effected without much difficulty or delay, and further that a party, once landed, might with safety winter at such a spot, where the penguins would furnish an abundant supply of food and fuel. A properly equipped party of observers situated at a point like this on the Antarctic continent for one or two winters might carry out a most valuable series of scientific observations, make sucessful excursions towards the interior, and bring back valuable information as to the probable thickness of the ice-cap, its temperature at different levels, its rate of accumulation, and its motions, concerning all which points there is much difference of opinion among scientific men.

Antarctic Land.

Is there an Antarctic continent? It has already been stated that the form and structure of the Antarctic icebergs indicate that they were built up on, and had flowed over, an extended land surface. As these bergs are floated to the north and broken up in warmer latitudes they distribute over the floor of the ocean a large quantity of glaciated rock fragments and land detritus. These materials were dredged up by the *Challenger* in considerable quantity, and they show that the rocks over which the Antarctic land-ice moved were gneisses, granites, mica-schists, quartziferous diorites, grained quartzites, sandstones, limestones, and shales. These lithological types are distinctively indicative of continental land, and there can be no doubt about their having been transported from land situated towards the South Pole. D'Urville describes rocky islets off Adélie Land composed of granite and gneiss. Wilkes found on an iceberg, near the same place, boulders of red sandstone and basalt. Borchgrevink and Bull have brought back fragments of mica-schists and other continental rocks from Cape Adare. Dr. Donald brought back from Joinville Island a piece of red jasper or chert containing Radiolaria and Sponge spicules. Captain Larsen brought from Seymour Island pieces of fossil coniferous wood, and also fossil shells of *Cucullæa*, *Cytherea*, *Cyprina*, *Teredo*, and *Natica*, having a close resemblance to species known to occur in lower Tertiary beds in Britain and Patagonia. These fossil remains indicate in these areas a much warmer climate in past times. We are thus in possession of abundant indications that there is a wide extent of continental land within the ice-bound regions of the southern hemisphere.

---

[1] Address by Dr. John Murray, F.R.S., and subsequent speeches, delivered at a special meeting of the Royal Society on February 24.

It is not likely that any living land-fauna will be discovered on the Antarctic continent away from the penguin rookeries. Still, an Antarctic expedition will certainly throw much light on many geological problems. Fossil finds in high latitudes are always of special importance. The pieces of fossil wood from Seymour Island can hardly be the only relics of plant life that are likely to be met with in Tertiary and even older systems within the Antarctic. Tertiary, Mesozoic, and Palæozoic forms are tolerably well developed in the Arctic regions, and the occurrence of like forms in the Antarctic regions might be expected to suggest much as to former geographical changes, such as the extension of the Antarctic continent towards the north, and its connection with, or isolation from, the northern continents, and also as to former climatic changes, such as the presence in pre-Tertiary times of a nearly uniform temperature in the waters of the ocean all over the surface of the globe.

Magnetic and Pendulum Observations, Geodetic Measurements, Tides and Currents.

In any Antarctic expedition magnetic observations would, of course, form an essential part of the work to be undertaken, and the importance of such observations has been frequently dwelt upon by eminent physicists and navigators. Should a party of competent observers be stationed at Cape Adare for two years, pendulum observations could be carried out there and at other points within the Antarctic, or even on icebergs and on the interior ice-cap. It might be possible to measure a degree on the Antarctic continent or ice-cap, which would be a most useful thing to do. By watching the motions of the icebergs and ice from land at Cape Adare, much would be learnt about oceanic currents, and our knowledge of the tides would be increased by a systematic series of tidal observations on the shores of Antarctica, where we have at present no observations. The series of scientific observations here mentioned, and others that might be indicated, would fill up many gaps in our knowledge of the physical conditions of these high southern latitudes.

Depth of the Antarctic Ocean.

In regard to the depth of the ocean immediately surrounding the Antarctic continent we have at present very meagre information, and one of the objects of an Antarctic expedition would be to supplement our knowledge by an extensive series of soundings in all directions throughout the Antarctic and Southern Oceans. It would in this way be possible, after a careful consideration of the depths and marine deposits, to trace out approximately the outlines of the Antarctic continent. At the present time we know that Ross obtained depths of 100 to 500 fathoms all over the great bank extending to the east of Victoria Land, and somewhat similar depths have been obtained extending for some distance to the east of Joinville Island. Wilkes sounded in depths of 500 and 800 fathoms about twenty or thirty miles off Adélie Land. The depths found by the *Challenger* in the neighbourhood of the Antarctic circle were from 1300 to 1800 fathoms, and further north the *Challenger* soundings ranged from 1260 to 2600 fathoms. To the south-west of South Georgia, Ross paid out 4000 fathoms of line without reaching bottom. In the charts of depth which I have constructed, I have always placed a deep sea in this position; for it appears to me that Ross, who knew very well how to take soundings, was not likely to have been mistaken in work of this kind.

The few indications which we thus possess of the depth of the ocean in this part of the world seem to show that there is a gradual shoaling of the ocean from very deep water towards the Antarctic continent, and, so far as we yet know, either from soundings or temperature observations, there are no basins cut off from general oceanic circulation by barriers or ridges, similar to those found towards the Arctic.

Deposits of the Antarctic Ocean.

The deposits which have been obtained close to the Antarctic continent consist of blue mud, containing glauconite, made up for the most part of detrital matters brought down from the land, but containing a considerable admixture of the remains of pelagic and other organisms. Further to the north there is a very pure diatom ooze, containing a considerable quantity of detrital matter from icebergs, and a few pelagic foraminifera. This deposit appears to form a zone right round the earth in these latitudes. Still farther to the north the deposits pass in deep water, either into a Globigerina ooze, or into a red clay with manganese nodules, sharks' teeth, ear-bones of whales, and the other materials characteristic of that deep-sea deposit. Since these views, however, as to the distribution of deep-sea deposits throughout these high southern latitudes, are founded upon relatively few samples, it cannot be doubted that further samples from different depths in the unexplored regions would yield most interesting information.

Temperature of the Antarctic Ocean.

The mean daily temperature of the surface waters of the Antarctic, as recorded by Ross, to the south of latitude 63° S. in the summer months, varies from 27·3° to 33·6°, and the mean of all his observations is 29·85°. As already stated, his mean for the air during the same period is somewhat lower, being 28·74°. In fact, all observations seem to show that the surface water is warmer than the air during the summer months.

The *Challenger* observations of temperature beneath the surface indicate the presence of a stratum of colder water wedged between warmer water at the surface, and warm water at the bottom. This wedge-shaped stratum of cold water extends through about 12° of latitude, the thin end terminating about latitude 53° S., its temperature varying from 28° at the southern thick end to 32·5° at the northern thin end, while the temperature of the overlying water ranges from 29° in the south to 38° in the north, and that of the underlying water from 32° to 35°. This must be regarded as the distribution of temperature only during the summer, for it is improbable that during the winter months there is a warmer surface layer.

In the greater depths of the Antarctic, as far south as the Antarctic circle, the temperature of the water varies between 32° and 35° F., and is not, therefore, very different from the temperature of the deepest bottom water of the tropical regions of the ocean. The presence of this relatively warm water in the deeper parts of the Antarctic Ocean may be explained by a consideration of general oceanic circulation. The warm tropical waters which are driven southwards along the eastern coasts of South America, Africa, and Australia into the great all-encircling Southern Ocean, there become cooled as they are driven to the east by the strong westerly winds. These waters, on account of their high salinity, can suffer much dilution with Antarctic water, and still be denser than water from these higher latitudes at the same temperature. Here the density observations and the sea-water gases indicate that a large part of the cold water found at the greater depths of the ocean probably leaves the surface and sinks towards the bottom in the Southern Ocean, between the latitudes of 45° and 56° S. These deeper, but not necessarily bottom, layers are then drawn slowly northwards towards the tropics, to supply the deficiencies there produced by evaporation and southward-flowing surface currents, and these deeper layers of relatively warm water appear likewise to be slowly drawn southwards to the Antarctic area to supply the place of the ice-cold currents of surface water drifted to the north. This warm underlying water is evidently a potent factor in the melting and destruction of the huge table-topped icebergs of the southern hemisphere. While these views as to circulation of oceanic water appear to be well established, still a fuller examination is most desirable at different seasons of the year, with improved thermometers and sounding machines. Indeed, all deep-sea apparatus has been so much improved as a result of the *Challenger* explorations, that the labour of taking salinity and all other oceanographical observations has been very much lessened.

Pelagic Life of the Antarctic Ocean.

In the surface waters of the Antarctic there is a great abundance of diatoms and other marine algæ. These floating banks or meadows form primarily not only the food of pelagic animals, but also the food of the abundant deep-sea life which covers the floor of the ocean in these south polar regions. Pelagic animals, such as copepods, amphipods, molluscs, and other marine creatures, are also very abundant, although species are fewer than in tropical waters. Some of these animals seem to be nearly, if not quite, identical with those found in high northern latitudes, and they have not been met with in the intervening tropical zones. The numerous species of shelled Pteropods, Foraminifera, Coccoliths, and Rhabdoliths, which exist in the tropical surface waters, gradually disappear as we approach the Antarctic circle, where the shelled Pteropods are represented by a small *Limacina*, and the Foraminifera by only two species of *Globigerina*, which are apparently identical with those in the Arctic Ocean. A peculiarity of the tow-net gatherings made by the *Challenger* Expedition in high southern latitudes, is the great rarity or absence of the pelagic larvæ of benthonic organisms, and in this respect they agree with similar collections from the cold waters of the Arctic seas. The absence of these larvæ from polar waters may be accounted for by the mode of development of benthonic animals to be referred to presently. It must be remembered that many of these pelagic organisms pass most of their lives in water of a temperature below 32° F., and it would be most interesting to learn more about their reproduction and general life-history.

Benthos Life of the Antarctic Ocean.

At present we have no information as to the shallow-water fauna of the Antarctic continent; but, judging from what we do know of the off-lying Antarctic islands, there are relatively few species in the shallow waters in depths less than 25 fathoms. On the other hand, life in the deeper waters appears to be exceptionally abundant. The total number of species of Metazoa collected by the *Challenger* at Kerguelen in depths less than 50 fathoms was about 130, and the number of additional species known from other sources from the shallow waters of the same island is 112, making altogether 242 species, or 30 species less than the number obtained in eight deep hauls with the trawl and dredge in the Kerguelen region of the Southern Ocean, in depths exceeding 1260 fathoms, in which eight hauls 272 species were obtained. Observations in other regions of the Great Southern Ocean, where there is a low mean annual temperature, also show that the marine fauna around the land in high southern latitudes appears to be very poor in species down to a depth of 25 fathoms, when compared with the number of species present at the mud-line about 100 fathoms, or even at depths of about 2 miles.

In 1841 Sir James Ross stated that the animals he dredged off the Antarctic continent were the same as those he had dredged from similar depths in the Arctic Seas, and he suggested that they might have passed from the one pole to the other by way of the cold waters of the deep sea.[1] Subsequent researches have shown that, as with pelagic organisms, many of the bottom-living species are identical with, or closely allied to, those of the Arctic regions, and are not represented in the intermediate tropical areas. For instance, the most striking character of the shore-fish fauna of the Southern Ocean is the reappearance of types inhabiting the corresponding latitudes of the northern hemisphere, and not found in the intervening tropical zone. This interruption of continuity in the distribution of shore-fishes is exemplified by species as well as genera, and Dr. Günther enumerates eleven species and twenty-nine genera as illustrating this method of distribution. The following are among the species:—Chimæra (*Chimæra monstrosa*), two species of Dog-fish (*Acanthias vulgaris* and *A. Blainvilli*), the Monk-fish (*Rhina squatina*), John Dory (*Zeus faber*), Angler (*Lophius piscatorius*), Bellows-fish (*Centriscus scolopax*), Sprat (*Clupea sprattus*). The genus by which the family Berycidæ is represented in the southern temperate zone (*Trachichthys*) is much more nearly allied to the northern than to the tropical genera. "As in the northern temperate zone, so in the southern . . . the variety of forms is much less than between the tropics. This is especially apparent on comparing the number of species constituting a genus. In this zone, genera composed of more than ten species are the exception, the majority having only from one to five." . . . "*Polyprion* is one of those extraordinary instances in which a very specialised form occurs at almost opposite points of the globe, without having left a trace of its previous existence in, or of its passage through, the intermediate space."

Speaking of the shore-fishes of the Antarctic Ocean, Günther says: "The general character of the fauna of Magelhæn's Straits and Kerguelen's Land is extremely similar to that of Iceland and Greenland. As in the Arctic fauna, Chondropterygians are scarce, and represented by *Acanthias vulgaris* and species of *Raja*. . . . As to Acanthopterygians, Cataphracti, and Scorpænidæ are represented as in the Arctic fauna, two of the genera (*Sebastes* and *Agonus*) being identical. The Cottidæ are replaced by six genera of Trachinidæ, remarkably similar in form to Arctic types. . . . Gadoid fishes reappear, but are less developed; as usual they are accompanied by *Myxine*. The reappearance of so specialised a genus as *Lycodes* is most remarkable."[2]

These statements with reference to shore-fishes might, with some modifications, be repeated concerning the distribution and character of all classes of marine invertebrates in high northern and high southern latitudes. The *Challenger* researches show that nearly 250 species taken in high southern latitudes occur also in the northern hemisphere, but are not recorded from the tropical zone. Fifty-four species of sea-weeds have also been recorded as showing a similar distribution.[1] Bipolarity in the distribution of marine organisms is a fact, however much naturalists may differ as to its extent and the way in which it has originated.

All those animals which secrete large quantities of carbonate of lime greatly predominate in the tropics, such as Corals, Decapod Crustacea, Lamellibranchs, and Gasteropods. On the other hand, those animals in which there is a feeble development of carbonate of lime structures predominate in cold polar waters, such as Hydroida, Holothuroidea, Annelida, Amphipoda, Isopoda, and Tunicata. This difference is in direct relation with the temperature of the water in which these organisms live, carbonate of lime being thrown down much more rapidly and abundantly in warm than in cold water by ammonium carbonate, one of the waste products of organic activity.

In the Southern and Sub-antarctic Ocean a large proportion of the Echinoderms develop their young after a fashion which precludes the possibility of a pelagic larval stage. The young are reared within or upon the body of the parent, and have a kind of commensal connection with her till they are large enough to take care of themselves. A similar method of direct development has been observed in eight or nine species of Echinoderms from the cold waters of the northern hemisphere. On the other hand, in temperate and tropical regions, the development of a free-swimming larva is so entirely the rule that it is usually described as the normal habit of the Echinodermata. This similarity in the mode of development between Arctic and Antarctic Echinoderms (and the contrast to what takes place in the tropics) holds good also in other classes of Invertebrates, and probably accounts for the absence of free-swimming larvæ of benthonic animals in the surface gatherings in Arctic and Antarctic waters.

What is urgently required with reference to the biological problems here indicated is a fuller knowledge of the facts, and it cannot be doubted that an Antarctic expedition would bring back collections and observations of the greatest interest to all naturalists and physiologists, and without such information it is impossible to discuss with success the present distribution of organisms over the surface of the globe, or to form a true conception of the antecedent conditions by which that distribution has been brought about.

Concluding Remarks.

There are many directions in which an Antarctic Expedition would carry out important observations besides those already touched on in the foregoing statement. From the purely exploratory point of view much might be urged in favour of an Antarctic Expedition at an early date; for the further progress of scientific geography it is essential to have a more exact knowledge of the topography of the Antarctic regions. This would enable a more just conception of the volume relations of land and sea to be formed, and in connection with pendulum observations some hints as to the density of the sub-oceanic crust and the depth of the Antarctic ice-cap might be obtained. In case the above sketch may possibly have created the impression that we really know a great deal about the Antarctic regions, it is necessary to re-state that all the general conclusions that have been indicated are largely hypothetical, and to again urge the necessity for a wider and more solid base for generalisations. The results of a successful Antarctic Expedition would mark a great advance in the philosophy—apart from the mere facts—of terrestrial science.

No thinking person doubts that the Antarctic will be explored. The only questions are: when? and by whom? I should like to see the work undertaken at once, and by the British Navy. I should like to see a sum of 150,000*l.* inserted in the estimates for the purpose. The Government may have sufficient grounds for declining to send forth such an expedition at the present time, but that is no reason why the scientific men of the country should not urge that the exploration of the Antarctic would lead to important additions to knowledge, and that, in the interests of science among English-speaking peoples, the United Kingdom should take not only a large but a leading part in any such exploration.

The Antarctic Ice-sheet: Duke of Argyll.

Scientific men generally feel, I think, that they do not need to give detailed reasons in connection with particular subjects of inquiry, to justify their unanimous desire for an Antarctic Expedition. It is enough, surely, for them to point out the fact that a very large area of the surface of our small planet is still almost unknown to us. That it should be so seems almost a reproach to our civilisation. As to detailed reasons, it may almost be said with truth that there is hardly one of the physical sciences on which important light may not be cast by Antarctic exploration. Oceanic circulation; meteorology; magnetism; distribution of animal and vegetable life, not only in the present but in the past; geology; mineralogy; volcanic action under special conditions—all of these are subjects on which the phenomena of the Antarctic regions are sure to bear directly.

If, however, I am asked to specify more particularly the question on which I look for invaluable evidence which can be got nowhere else, I must name, above all others, the most difficult questions involved in quaternary geology. Geologists are nearly all agreed that there has been, very recently, a glacial age—an age in which glacial conditions prevailed over the whole northern hemisphere to a much lower latitude than they prevail now. But geologists differ widely and fundamentally from each other as to the form which glacial agencies took during that period. In particular, many geologists believe in what they call an "ice sheet"—that is to say, in the northern world having been covered by an enormous mass of ice several thousand feet thick, which, as they assert, "flowed" over mountain areas as well as over plains, and filled up the bed of seas of a considerable depth. Other geologists disbelieve in this agency altogether. They deny that even such a body of ice ever existed; it could not possibly have moved in the way which the theory assumes. They affirm, also, that the facts connected with glaciated surfaces do not indicate the planing down by one universal sheet of enormous weight and pressure; but, on the contrary, the action of small and lighter bodies of ice, which have acted partially and unequally on different surfaces differently exposed.

We might have hoped that this controversy could be settled by the facts connected with the only enormous ice-sheet which exists in the northern hemisphere, viz. that which covers the great continent of Greenland. But that ice-sheet, enormous though it be, does certainly not do what the ice-sheet of the Glacial Age is supposed to have done. That is to say, it does not flow out from Greenland, fill the adjacent seas, or override the opposite coasts, even in so narrow a sheet as Smith's Sound. But this evidence is negative only. In the Antarctic continent we have reason to believe that there is a larger ice-sheet, and it certainly does protrude into the adjacent seas, not merely by sending out broken, floating fragments, but in unbroken ice cliffs of great height. Now we want to know exactly under what conditions this protrusion takes place. Dr. Murray speaks of it as "creeping" seawards—a more cautious word than "flowing." But is it certain that it does even creep? May it not simply grow by accretion or aggregation till it reaches a depth of water so great as to break it off by flotation? Does it, or does it not, carry detritus when no detritus has been dropped on its surface? Or does it pick up detritus from its own bed? Or does it push foreign matter before it? Does the perfectly tabular form of the Antarctic icebergs indicate any differential movement in the parent mass at all; or does it not indicate a condition of immobility until their buoyancy lifts great fragments off? What is the condition of the rocks on which they rest? Is there any thrust upon the mass from the mountain ranges on which the gathering ground lies? Or is the whole country one vast gathering ground from the continual excess of precipitation over melting? These questions, and a hundred others, have to be solved by Antarctic discovery; and until they are solved we cannot argue with security on the geological history of our own now temperate regions. The Antarctic continent is unquestionably the region of the earth in which glacial conditions are at their maximum, and therefore it is the region in which we must look for all the information attainable towards, perhaps, the most difficult problem with which geological science has to deal.

Sir Joseph Hooker's Views.

Dr. Murray's admirable summary of the scientific information obtainable by an organised exploration of the Antarctic regions, leaves nothing further to be said under that head. I can only record the satisfaction with which I heard it, and my earnest hope that it will lead to action being taken by the Government in the direction indicated.

Next to a consideration of the number and complexity of the objects to be obtained by an Antarctic Expedition, what dwells most in my imagination, is the vast area of the unknown region which is to be the field for investigation—a region which, in its full extension, reaches from the latitude of 60° S. to the Southern Pole, and embraces every degree of longitude. This is a very considerable portion of the surface of the globe, and it is one that has been considered to be for the most part inaccessible to man; I will, therefore, ask you to accompany the scientific explorer no further than to the threshold of the scenes of his labours, that you may see how soon and how urgently he is called upon to study some of those hitherto unsolved Antarctic problems that he will there encounter.

In latitude 60° S. an open ocean girdles the globe without break of continuity. Proceeding southwards in it, probably before reaching the Antarctic Circle, he encounters the floating ice fields which form a circumpolar girdle known as "The Pack" approximately concentric with the oceanic, interrupted in one meridian only, that south of Cape Horn, by the northern prolongation of Graham's Land. Pursuing his southward course in search of seas or lands beyond, after the novelty of his position in the Pack has worn off, he asks where and how the component parts of these great fields of ice had their origin, how they arrived at, and maintain their present position, what are their rate of progress and courses, and what their influence on the surrounding atmosphere and ocean. I believe I am right in thinking that to none of these questions can a fuller answer be given, than that they originated over extensive areas of open water in a higher latitude than they now occupy, that they are formed of frozen ocean water and snow, and that winds and currents have brought them to where we now find them. But of the position of the southern, open waters, with the exception of the comparatively diminutive sea east of Victoria Land,[1] we know nothing, nor do we know anything of the relative amount of snow and ice of which they are composed, or of their age, or of the winds and currents that have carried them to a lower latitude.

The other great glacial feature of the Antarctic area is "The Barrier," which Ross traced for 300 miles in the 78th and 79th degree of south latitude, maintaining throughout its character of an inaccessible precipitous ice-cliff (the sea-front of a gigantic glacier) of 150 to 200 feet in height. This stupendous glacier is no doubt one parent of the huge table-topped ice-islands that infest the higher latitudes of the Southern Ocean; but as in the case of the Pack, we do not know where the Barrier has its origin, or anything further about it than that it in great part rests upon a comparatively shallow ocean bottom. It probably abuts upon land, possibly on an Antarctic continent; but to prove this was impossible, on the occasion of Ross's visit, for the height of the ship's crow's-nest above the sea-surface was not sufficient to enable him to overlook even the upper surface of the ice. Nor do I foresee any other method of settling this important point, except by the use of a captive balloon, an implement with which I hope that future expeditions may be supplied. There were several occasions in which such an implement might advantageously have been used by Ross when near the Barrier, and more when it would have greatly facilitated his navigation of the Pack

I have chosen the Antarctic Ice as the subject upon which to address this most important meeting, not only because it is one of the very first of the phenomena that demand the study of the explorer, but because it is the dominant feature in Antarctic navigation, where the Pack is ever present or close by, demanding, whether for being penetrated or evaded, all the commander's fortitude and skill, and all his crew's endurance.

It may be expected that I should allude to those sections of Dr. Murray's summary that refer to the Antarctic fauna and flora; they are most important, for the South Polar Ocean swarms with animal and vegetable life. Large collections of these, taken both by the tow-net and by deep sea soundings, were made by Sir J. Ross, who was an ardent naturalist and threw away no opportunity of observing and preserving; but unfortunately, with the exception of the Diatomaceæ (which were investigated by

---

[1] I refer to the "pancake" ice, which, in that sea, on several occasions formed with great rapidity around Ross's ships, in lat. 76° to 78° S. in February 1842, and which arrested their progress. Such ice, augmented by further freezing of the water and by snowfalls, may be regarded as a genesis of fields that, when broken up by gales, are carried to the north and contribute to the circumpolar Pack.

Ehrenberg), very few of the results of his labour in this direction have been published. A better fate, I trust, awaits the treasures that the hoped-for expedition will bring back; for so prolific is that ocean, that the naturalist need never be idle, no, not even for one of the twenty-four hours of daylight throughout an Antarctic summer, and I look to the results of a comparison of the oceanic life of the Arctic and Antarctic regions as the heralding of an epoch in the history of biology.

The Practicability of Antarctic Exploration.

Dr. Nansen said a great Antarctic Expedition should be undertaken by the British nation. He confined his observations to the great importance of a land expedition in the Antarctic continent. It would certainly be of the highest importance to have it in connection with a naval expedition, which would afford an excellent basis for such a land expedition. Dr. Murray had already mentioned the possibilities, and perhaps probabilities, that there was a large Antarctic continent covered by an ice-cap. They did not quite know yet. It might be that there were large islands, and there might be sounds in between covered with floating ice. Whether that was so or not, it was certain there must be one or several huge ice-caps inside this unknown territory in the South, and he felt certain that the exploration of these would give scientific information of the greatest importance. There were many problems to solve, and the only place they could try to solve them in was the polar regions. Greenland had already given them much information about the ice-sheet, but Greenland was too small, when compared with the big ice-sheets in the glacial packs. They should look to the much more extensive ice-sheets which they might find in the unknown territory. He did not think it would be very difficult to reach the Antarctic continent. They must remember they knew a great deal more about ice investigation than in the days of Ross. They had much better ships, and had steam, and were not afraid to push the ships into an ice-pack. They knew that if they were exposed to pressure and some hard times, they had the means to get out of it again; and his opinion was that in the Southern sea they were surrounded by much open water all round, and a ship would not run the risk of being shut up in ice as long as in the Arctic regions, where the seas were shut up by land round about. So far as he understood it, they would not run so much risk in that way in the South as in the Arctic. The ice generally opened in calm weather, and that was exactly when sailing-vessels would not be able to make use of the opportunity to get in. So he thought with their modern steamships it would not be difficult to get into the Antarctic. It had been said that the ice-sheet in the Antarctic continent was difficult to get at. It was difficult to ascend. Of course, when they went along the Barrier, as Ross did, it was difficult to get through, and probably the only way would be by captive balloons. He believed captive balloons would be of the greatest use for exploration in Polar regions. With regard to the probable thickness of the ice-sheet in the Antarctic, some put it at 2000 feet, some at 10,000 feet, but he would rather put it at 20,000 feet. The height might present considerable difficulty to any land expedition. This enormous ice-sheet must have an important influence upon the climatology of the whole world, and valuable information might be obtained as to meteorological conditions through an Antarctic expedition. If such a great naval expedition as had been suggested were sent from this country, Norway would gladly join in the work and send out another expedition to take part in the land work, and it would be of the greatest importance if there could be international co-operation in these expeditions, because simultaneous observations could then be made in these Antarctic regions, and they could lay their plans in a more scientific way.

Dr. Neumayer on Gravity and Terrestrial Magnetism.

A gravity survey is, in connection with a thorough geographical survey of the Antarctic, one of the most urgent requirements of the science of our earth. There are no measurements of the gravity constant within the Antarctic region; indeed, they are very scarce in the southern hemisphere south of 30° lat. S., and they are so closely connected with the theory of the figure of our earth that it is hardly possible to arrive at any conclusive results in this all-important matter without observations within the Antarctic region. It is impossible to foretell what effect an exact gravity survey in that region might exert upon our views with regard to all physical elements which depend upon the radius of our earth. Apart from that consideration, we may hope for another important enlargement of the knowledge bearing upon the connection between terrestrial magnetism and gravity. Gravity observations have been so much simplified of late, by von Herack's ingenious apparatus, that it does not offer a serious difficulty to multiply gravity determinations within the Antarctic region, so that we may well be able to speak of a "gravity survey." The all-important question of the distribution of land within the South Polar region is closely connected with it. The International Geodetic Permanent Commission expressed it as their conviction that a gravity survey within that region would be of the greatest benefit for higher geodetic theories.

The probable connection between gravity and terrestrial magnetism has already been referred to. But apart from this, a magnetic survey of the Antarctic region is of the greatest importance from other points of view. As, since the time of Ross, no other observations of the values of the magnetic elements have been made, we are perfectly ignorant of the values of the secular variations south of 50° lat., though this information is urgently needed for the construction of trustworthy magnetic charts required in navigation. Of the situation of the southern magnetic pole, and of its motion during the last fifty years, we are equally ignorant, though the facts are so highly important according to Gauss's theoretical deductions.

Much as the mathematical theory of terrestrial magnetism has been developed, of the physical theory of that mysterious force in nature we are yet in perfect ignorance. This defect is certainly to some considerable degree caused by the want of our knowledge in higher latitudes. It seems as if the magnetic character of the South Polar region is such as would afford all facility for a sound investigation when compared with the magnetic conditions of the North Polar region. A glance at a magnetic map shows how entirely different is the distribution of the magnetic action in both polar regions.

There is the interesting fact to be noticed in the south that the two foci of total intensity are situated on the side towards the south of the Australian continent, and nearly on the same meridian. The magnetic action which makes itself manifest by magnetic storms or disturbances reaches its highest degree likewise south of the Australian continent, whereas to the south of South America the storms become very scarce and of a similar magnitude to those in middle latitudes. This was most strikingly proved by the observations in Orange Bay and South Georgia during the period of international observations in 1882-83. Of course the magnetic south pole and the situation of the foci above mentioned, are in close connection with these facts, but the reason of their distribution remains unexplained. A discussion of all observations on southern polar lights also shows a connection between their frequency and the maximum region of magnetic disturbance.

Though the examination of these few facts ought to prompt the institution of a vigorous examination of the south polar regions, the series is far from being exhausted: there is the question of the geoid-deformation, the phenomena of the tides, and the structure of the ice and its drifting.

The resolution of the Sixth International Geographical Congress that the present century should not be allowed to expire without unveiling the mysteries of the south polar regions, ought to be carried into effect. All scientific institutions and societies trust that such will take place without any further delay.

Sir Clements Markham on Antarctic Geography.

I need scarcely say how fully I concur in every word that has fallen from Dr. Murray on the subject of the scientific results, and more especially of the geographical results of an Antarctic Expedition.

It is sufficient to point out the vast extent of the unknown area, and that no area of like extent, on the surface of the earth, ever failed to yield results of practical, as well as of purely scientific interest by its exploration.

But there is much more to be said in the present instance: because the little that we do know of the Antarctic regions points unerringly to the very great importance and interest of the results that are certain to attend further research.

The ice barrier, discovered by Sir James Ross, is known to be the source of the immense ice islands of the southern polar sea. But it has only been seen for a distance of 300 miles. It requires far more complete examination before any approach to an adequate knowledge can be obtained, respecting the extent and nature of the supposed ice-cap in its rear.

We know that the southern continent is a region of actual volcanic activity; but the extent, nature, and effect of that activity remain to be ascertained.

On the Antarctic Circle land has been reported at numerous points, south of Australia and the Indian ocean, but it is unknown whether what has been seen indicates islets and rocks, or a continuous coast-line.

Dr. Murray has pointed out that the whole southern continent is certainly not bounded by such an ice-wall as was seen by Sir James Ross, and is not covered by an ice-cap. But the extent alike of the ice-cap and of the uncovered land is unknown.

We are ignorant of the distribution of land and sea, and of ice and water in summer, and of the causes which influence such distribution.

These are some of the geographical problems to be solved. The investigation of each one of them will lead to further discoveries as yet undreamt of, which must needs be of the deepest interest to geographers.

There are eminent men present who will no doubt refer to the results of Antarctic exploration as regards other branches of science. Combined together they make the discovery of the unknown parts of the Antarctic region the greatest and most important work that remains for this generation of explorers to achieve.

METEOROLOGY AND ANTARCTIC EXPLORATION.

Dr. Alexander Buchan stated that the remarks he was about to make would have exclusive reference to the first two paragraphs of Dr. Murray's address, under the heading of "The Atmosphere"; or, rather, more immediately to the relation between mean atmospheric pressure and prevailing winds. He supposed he had been asked to speak on this occasion, from the extensive and minute knowledge of the subject he had necessarily acquired in the preparation of the reports on atmospheric and oceanic circulation which were published as two of the reports of the scientific results of the voyage of H.M.S. *Challenger*.

The former of these reports, on atmospheric circulation, is accompanied by twenty-six maps, showing by isobars for each month and the year the mean pressure of the atmosphere, and by arrows the prevailing winds of the globe, on hypsobathymetric maps, or maps showing by shadings the height of the land and the depth of the sea; first on Gall's projection, and second on north circumpolar maps on equal surface projection. The isobars are drawn from mean pressures calculated for 1366 places, and the winds from even a larger number of places, distributed as well as possible over the whole globe. It is also of importance to note that averages of pressure and prevailing winds are published with the report—an accompaniment to the maps of mean atmospheric pressure and prevailing winds of the globe not yet given in any other series of maps of mean pressure and prevailing winds.

This then is the work undertaken and published in these reports, which occupied seven years in preparing, as time could be spared from official duties. The result of the charting of the pressure and prevailing winds is this: stand with your back to the wind, then the centre of lowest pressure that causes the wind will be to the left in the northern hemisphere, and to the right hand in the southern hemisphere, a relation well known as Buys Ballot's law. In charting the 1366 pressures and the relative prevailing winds, no exception was found in any of the two hemispheres. This is one of the broadest generalisations science can point to.

Some years ago a theory of atmospheric circulation was published by the late Prof. Ferrel which, as it is not accordant with the broad results arrived at in the report of atmospheric circulation in the *Challenger* Reports, calls for serious consideration on account of its bearing on any attempt proposed to be undertaken for the exploration of the Antarctic regions.

One of the more recent expositors of this theory is Prof. Davis, of Harvard College, who, in his "Elementary Meteorology," gives an admirable exposition of the results now arrived at by the various workers in meteorology, and of the opinions and theories promulgated by different meteorologists in different departments of the science. The book is largely used in secondary schools and colleges of the United States, and these views are all but universally held there, and are now spreading over other countries.

The following extracts from Davis's book fairly represent these views as generally entertained.

"The surface winds of the temperate latitudes, and the high-level currents above them, sliding swiftly along on their steep poleward gradients, must all be considered together. They combine to form a vast aerial vortex or eddy around the pole. In the northern hemisphere this great eddy is much interrupted by continental high pressure in winter, or low pressure in summer, and by obstruction from mountain ranges, as well as by irregular disturbances of the general circulation in the form of storms" (p. 110).

Now the facts of observation do not support the theory of the existence, at any season of the year, of a low barometric pressure, or an eddy of winds, round or in the neighbouring regions of the north pole. Observations do not show us any prevailing winds blowing homewards to the north pole at any time of the year. Further, no low barometric pressure occupies the immediate polar region in any month; but instead, the opposite holds good for the four months from April to July. In April and May the mean atmospheric pressure is higher in the region of the pole than it is anywhere in the northern hemisphere north of 43° lat. N.; and in June and July, also higher than it is anywhere north of 55° lat. N. Now the higher pressure in these four months necessitates the existence of upper currents in order to maintain this high pressure about the north pole. These upper currents toward the pole are exactly opposed to the requirements of the theory, which intimates that the upper currents in the region of the pole must necessarily blow not towards but from the pole.

The actual centre in this hemisphere, north of the tropics, towards which the winds on or near the surface of the earth blow, is not the north pole; but, in the winter months, the low barometric depressions in the north of the Atlantic and Pacific respectively, and in the summer months, the low barometric depressions in the Eurasian and North American continents; and the sources out of which the prevailing winds blow, in the winter months, the high pressure regions in Siberia and North America; and in the summer months, the high pressure regions lying northward of these continents, which, as already explained, are virtually the polar region itself. These are the facts in all regions where the winds, according to the theory, become winds blowing over the earth's surface.

As regards the southern hemisphere, Prof. Davis states that—

"In the southern hemisphere the circumpolar eddy is much more symmetrically developed." Again, "the high pressure that should result from the low polar temperatures is therefore reversed into low pressure by the excessive equatorward centrifugal force of the great circumpolar whirl; and the air thus held away from the polar regions is seen in the tropical belts of high pressure" (pp. 110, 111).

The interpretation of this is that the remarkable low pressure region of the southern hemisphere is continued southward to the south pole itself, the pressure diminishing all the way; and that in the region of the south pole, the air currents poured thitherwards along the surface of the earth, ascend, and thence proceed northwards as upper currents of such enormous intensity and volume, that they pile up in the tropical region of the southern hemisphere a mean sea-level atmospheric pressure about an inch and a half more than the sea-level pressure near the south pole whence it starts. Now, to bring the matter to the business which this meeting of the Royal Society has taken in hand—if this theory be true and supported by the facts of observation, it is plain that no meteorologist could signify his approval of any scheme that could be proposed for exploring the Antarctic regions, it being obvious that these strong west-north-westerly winds, if they blow vortically round and in upon the pole, heavily laden, as they necessarily would be with the aqueous vapour they have licked up from the Southern Ocean, would overspread Antartica with a climate of all but continuous rain, sleet, and snow, which no explorer, however intrepid and enthusiastic, could possibly face.

But is this the state of things? Let it be at once conceded that, as far south as about 55° lat. S., the prevailing winds and the steadily diminishing mean pressures on advancing southward fairly well support the theory. South of this, however, southerly and south-easterly winds begin to increase in frequency, until from 60° lat. S. into higher latitudes, they become the prevailing winds. This is abundantly shown from the winds charted on the maps of the *Challenger* Report, as well as from the unanimous experience of all those who have navigated this region from Ross to the present time. Thus the poleward blowing winds from west-north-west in these summer months stop short, at least, thirty degrees of latitude from the south pole.

These prevailing S.S.E. winds necessarily imply, as has been shown in the case of the north pole, the existence of a more or less pronounced anticyclone overspreading Antarctica; which in its turn necessarily implies the existence of upper currents from the northward, blowing towards and in upon the polar region to make good the drain caused by the surface out-blowing south-easterly winds. It may therefore be concluded that both the surface winds and the upper aerial currents are diametrically opposed to the requirements of this theory.

What is now urgently called for is a well-equipped Antarctic Expedition to make observations which will enable meteorologists to settle definitely the distribution of atmospheric pressure and the prevailing winds of this great region. Were this done, the position in the Southern Ocean of the great ring of lowest pressure that encircles the globe could be mapped out; and since it is towards this low-pressure ring that the wind-driven surface currents of the ocean flow, a contribution would thereby be made to oceanography, of an importance that cannot be over-estimated, particularly as regards the great question of oceanic circulation.

SIR ARCHIBALD GEIKIE ON ANTARCTIC GEOLOGY.

Hardly anything is yet known of the geology of the Antarctic regions. By far the most important contributions to our knowledge of the subject were made by the expedition under Sir James Ross. But as he was unable to winter with his ships in the higher latitudes, and could only here and there with difficulty effect a landing on the coast, most of the geological information brought home by him was gathered at a greater or less distance from the land, with the aid of the telescope. Within the last few years several sealing vessels have brought home some additional scraps of intelligence, which only increase the desire for fuller knowledge.

As regards the land, merely its edges have here and there been seen. Whether it is one great continent or a succession of islands and archipelagos may possibly never be ascertained. We know that in Victoria Land it terminates in a magnificent mountain-range with peaks from 10,000 to 15,000 feet high; but that elsewhere it is probably comparatively low, shedding its ice-cap in one vast sheet into the sea.

The rocks that constitute the land are still practically unknown. The dredgings of the *Challenger* Expedition brought up pieces of granite, gneiss, and other continental rocks, and detritus of these materials was observed to increase on the sea-floor southwards in the direction of the Antarctic land. More recently several sealing vessels have brought home from the islets of Graham Land to the south of the South Shetlands pieces of different varieties of granite, together with some volcanic rocks and fossiliferous limestones. So far as these rocks have been studied, they do not appear to differ from similar rocks all over the globe. The granites have been found by Mr. Teall to be just such masses as might have come from any old mountain group in Europe or America.

Among the specimens sent to me by Captain Robertson, of the *Active*, from Joinville and Dundee Islands, which form the north-eastern termination of Graham Land, there was one piece of reddish jasper which at once attracted my attention from its resemblance to the "radiolarian cherts" now found to be so widely distributed among the older Palæozoic rocks, both in the Old World and in the New. On closer examination, this first impression was confirmed; and a subsequent microscopic study of thin slices of the stone, by Dr. Hinde, proved the undoubted presence of abundant radiolaria. The specimen was a loose pebble picked up on the beach of Joinville Island. We have no means of telling where it came from, or what is its geological age. But its close resemblance to the radiolarian cherts so persistent in the Lower Silurian formations of the United Kingdom, raises the question whether there are not present in the Antarctic regions rocks of older Palæozoic age.

It would be of the utmost interest to discover such rocks *in situ*, and to ascertain how far their fossils agree with those found in deposits of similar antiquity in lower latitudes; or whether, as far back as early Palæozoic time, any difference in climate had begun to show itself between the polar and other regions of the earth's surface.

Among the specimens brought home by Dr. Donald and Captain Larsen from Seymour Island, in the same region, are a few containing some half-dozen species of fossil shells which have been named and described by Messrs. Sharman and Newton, who suggest that they point to the existence of Lower Tertiary rocks, one of the organisms resembling a form found in the old Tertiary formations of Patagonia. Large well-developed shells of *Cucullæa* and *Cytherea* undoubtedly indicate the former existence of a far milder climate in these Antarctic seas than now prevails.

If a chance landing for a few hours on a bare islet could give us these interesting glimpses into the geological past of the south polar regions, what would not be gained by a more leisurely and well-planned expedition?

But perhaps the geological domain that would be most sure to gain largely from such exploration would be that which embraces the wide and fascinating field of volcanic action. In the splendid harvest of results brought home by Sir James Ross, one of the most thrilling features was the discovery of a snowy volcanic cone rising amid the universal snows of Victoria Land to a height of more than 12,000 feet, and actively discharging "flame and smoke," while other lofty cones near it indicated that they too had once been in vigorous eruption. Ross landed on one or two islands near that coast, and brought away some pieces of volcanic rocks.

If we glance at a terrestrial globe we can readily see that the volcanic ring or "circle of fire," which nearly surrounds the vast basin of the Pacific Ocean, is prolonged southwards into New Zealand. The few observations that have been made in the scattered islands further south show that the Auckland, Campbell, and Macquarrie groups consist of, or at least include, materials of volcanic origin. Still further south, along the same general line, Mr. Borchgrevink has recently (1894-95) made known the extension of Ross's volcanic platorm northwards to Cape Adare, the northern promontory of Victoria Land. He noticed there the apparent intercalation of lava and ice, while bare snowless peaks seemed still further to point to the continued activity of the volcanic fires. Some specimens brought by his expedition from Possession Island, were found by Mr. Teall to be highly vesicular hornblende-basalt, while one from Cape Adare was a nepheline-tephrite. This region is probably one of the most interesting volcanic tracts on the face of the globe. Yet we can hardly be said to know more of it than its mere existence. The deeply interesting problems which it suggests cannot be worked out by transitory voyagers. They must be attacked by observers stationed on the spot. Ross thought that a winter station might be established near the foot of Mount Erebus, and that the interior could easily be traversed from there to the magnetic pole.

But it is not merely in Victoria Land that Antarctic volcanoes may be studied. Looking again at the globe, we observe that the American volcanic band is prolonged in a north and south line down the western side of the southern continent. That it has been continued into the chain of the South Shetlands and Graham Land is proved by the occurrence there of old sheets of basalt, rising in terraces over each other, sometimes to a height of more than 7000 feet above the sea. These denuded lavas may be as old as those of our Western Isles, Faroe, Iceland, and Greenland. But that volcanic activity is not extinct there has recently been found by Captain Larsen, who came upon a group of small volcanoes forming islets along the eastern coast-line of Graham Land. It is tantalising to know no more about them.

Another geological field where much fresh and important information might be obtained by Antarctic exploration is that of ice and ice-action. Our northern hemisphere was once enveloped in snow and ice, and though for more than half a century geologists have been studying the traces of the operations of this ice-covering, they are still far from having cleared up all the difficulties of the study. The Antarctic ice-cap is the largest in the world. Its behaviour could probably be watched along many parts of its margin, and this research would doubtless afford great help in the interpretation of the glaciation of the northern hemisphere.

To sum up:—Geologists would hail the organisation and despatch of an Antarctic Expedition in the confident assurance that it could not fail greatly to advance the interests of their science. Among the questions which it would help to elucidate, mention may be made of the following:—

The nature of the rocks forming the land of the Antarctic region, and how far these rocks contain evidence bearing on the history of terrestrial climates.

The extent to which the known fossiliferous formations of our globe can be traced towards the poles; the gaps which may occur between these formations and the light which their study may be able to throw on the evolution of terrestrial topography.

The history of volcanic action in the past, and the conditions under which it is continued now in the polar regions; whether in high latitudes vulcanism, either in its internal magmas or superficial eruptions, manifests peculiarities not observable nearer to the equator; what is the nature of the volcanic products now ejected at the surface; whether a definite sequence can be established from the eruptions of still active volcanoes back into those of earlier geological periods in Antarctic lands; and whether among the older sheets leaf-beds or other intercalations may be traceable, indicating the prolongation of a well-developed terrestrial flora towards the south pole.

The influence of the Antarctic climate upon the rocks exposed to its action; the effects of contact with ice and snow upon streams of lava; the result of the seaward creep of the ice-cap in regard to any lava-sheets intercalated in the ice. It is conceivable that portions of lava-streams might be broken off by the onward motion of the ice which they overspread, and might thus be carried out to sea, intercalated in or capping ice-bergs.

The physics of Antarctic ice in regard to the history of the Ice Age in northern Europe and America.

ANTARCTIC FAUNA.

Although an ardent advocate of Antarctic exploration, Mr. Sclater acknowledged that, as regards the higher vertebrates, with which he was most conversant, there was little chance of the discovery of new forms of animal life in the South Polar continent. The Antarctic mammals and birds (of the latter of which about twenty species were known) were exclusively of marine forms. Not a single land-mammal or land-bird had been yet obtained in Antarctica. As regards the class of fishes and the marine invertebrates, the case was quite different, and great discoveries might be anticipated in these groups, where very little had yet been done. The most promising zoological subject of Antarctic exploration seemed to him, however, to be the further investigation of the extinct fauna. The few fossil remains already obtained indicated the former existence in the South Polar area of a very different climate from that which now prevailed there, and further researches on this point might lead to most important results.

Prof. D'Arcy W. Thompson said that all we knew of the deep-sea life of the Antarctic came from eight hauls of the dredge, which hauls were, by common consent of the naturalists of the *Challenger*, the most productive of the whole cruise. The fauna of every ocean urgently demanded further exploration, for we knew now no more about the fauna of the deep-sea than was known a hundred years ago of the fauna of the shore. But the circumpolar fauna of the South, at the meeting of all the great oceans, presented problems of peculiar importance. He considered Dr. Murray's theory of a "bipolar fauna," closely akin both in the Arctic and Antarctic, as not proven; but he believed that there were many remarkable cases of continuous distribution, especially along the cold waters of the Western American coast from the Antarctic into the North Pacific, and even to Japan. If the "bipolar hypothesis" were broken down, Antarctic exploration would lead to new generalisations, not less interesting, to take its place.

Admiral Sir William Wharton said that an Antarctic Expedition must be under naval discipline. He hoped that such an expedition would not be far off, and he felt sure there would be a rush of officers and men to join it.

Sir John Evans, in briefly summing up the discussion, said it had maintained a high level, and that the meeting had been prolonged to an unprecedented hour in the Royal Society. All were agreed as to the immense advantages of an expedition, and he was sure it would find a warm advocate in the Hydrographer to the Admiralty.

ON THE ABSORPTION OF LIGHT BY FLUORESCING BODIES.[1]

MR. JOHN BURKE has recently given to the Royal Society of London (see NATURE, vol. lvi. p. 261) the result of some experiments which afford an important indication of the mode of action of bodies during fluorescence, and which may lead to a clearer conception of Kirchhoff's law on the equality of the emissive and absorptive powers of bodies

The following is one form of Mr. Burke's experiment:—A photographic plate, P (Fig. 1), is adjusted before two equal cubes of uranium glass, A and B, placed so that the light emanating from B is obliged to pass through A before reaching the photographic plate P.

The source of light, S, rich in the ultra-violet, illuminates the cubes by rays parallel to the plate, which is screened from the direct action of the source. An image is first formed by letting the exciting rays act on the two cubes simultaneously. The plate is then displaced, and a second image is produced by illuminating each of the cubes separately, each for the same length of time as in the first experiment.

The result is that on development the resultant impression of the two separate effects is always much more intense than that of the first due to the two conjointly.

The simplest explanation of this curious phenomenon is to suppose that the cube A absorbs the light emitted by the cube B more strongly when it is in a state of fluorescence than when it is screened from the exciting source. At first sight this property of fluorescent bodies appears to be a direct consequence of Kirchhoff's law, all luminous bodies absorbing the radiations which they are capable of emitting. But on looking at the matter more closely we find that this law, which includes so many facts, does not directly apply to the phenomenon discovered by Mr. Burke. This law states, in general, that all bodies, *at a given temperature*, have an emissive power and an absorptive power which are equal for each kind of radiation they emit. But we see here a class of bodies which, without having their temperature visibly altered, have their absorptive power changed, in consequence of the fact that, by a cause apparently different from an elevation of temperature, they emit, momentarily, and under the action of an external source, radiations which are extinguished at the same time as the excitation itself. By this excitation the molecule is not permanently altered, and it does not become susceptible of vibrating in unison with the light to which it had attained; but if, by an external cause, it is given this vibratory movement, then, and only then, it becomes a resonator for the radiations identically the same as that which it emits.

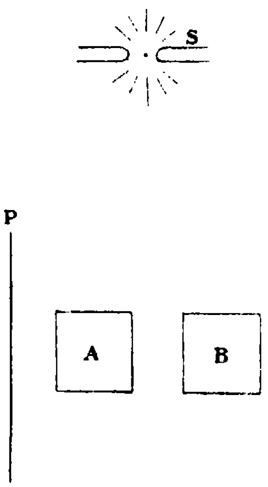

FIG. 1.

A familiar illustration will give us a more vivid conception of the mechanism of the phenomenon. Let us suppose a sound wave to approach a fixed tuning-fork of another pitch; the wave will pass on unabsorbed. But if we force the tuning-fork in such a way as to make it emit a note identical with that of the wave which approaches it, then it will behave as a resonator and will evidently become absorbent to the passing wave. The tuning-fork is thus capable of absorbing the vibratory energy which reaches it, not merely when the latter corresponds to its natural period of vibration, but also when it possesses a period identical with that of the forced vibration that is momentarily imparted to it.

It is probable, similarly, that the fluorescent molecules are excited momentarily to a forced vibration, and become, *for an instant*, susceptible of absorbing the vibrations of the same period.

It will be found, perhaps, that the familiar statement of Kirchhoff's law will apply, on comparing the small number of fluorescent molecules in the uranium glass, to any molecules whatsoever which have been raised to a fictitious temperature corresponding to their vibratory state. This extension of the notion of temperature has already been suggested with regard to various luminous phenomena other than that of incandescence, but it had merely led, up to the present, to the heaping up of difficulties without arriving at anything conclusive.

It seems to me far simpler to suppress the notion of *temperature* altogether in Kirchhoff's law, which is far too general to be limited by a conception that ought to have a precise and definite signification.

---

[1] Translation of a paper, by Prof. C. E. Guillaume, in the *Revue Générale des Sciences*, December 15, 1897.

THE STRUCTURE OF CRYSTALS.[1]

IT is impossible here to do more than call attention to these two memoirs; the subject with which they deal is too intricate to be intelligible without the aid of diagrams.

The author of the first appears to hold quite peculiar views on the nature of valency and chemical combination. Each atom is surrounded by a "sphere of action," and this represents the volume of the element; whereas the volume of a compound molecule is less than the sum of the volumes of its components, for their spheres of action are supposed to interpenetrate to a certain extent when combination takes place. Their partial interpenetration gives rise to a complex surface of action for the molecule, which may be of a polar character, and approximates in form to a sphere when the molecule consists of a large number of atoms. Crystallisation is due to the attractive juxtaposition of such polar molecules. For the author's general views the reader is referred to his previous work, "Die Kraft und Materie in Raume."

The present memoir is an elaborate study of the development of a number of complex forms by the superposition of spheres layer by layer on one or other of a few simple "embryos"; for example, on a tetrahedron composed of four equal spheres in contact. The whole process is illustrated by twenty six excellent plates, which appear to be photographs of skilfully constructed stacks of balls. On all matters the author expresses himself with remarkable confidence, and claims to have solved the problem of crystallisation.

We doubt, however, whether all the types of crystalline symmetry are covered by the author's hypotheses, and some of his groups appear to be incompatible with what is known of crystals.

Mr. Barlow's first communication on the subject of crystalline structure was made to this journal (vol. xxix. p. 186) in 1883, and was also illustrated by the regular grouping of spheres of different sorts. That paper was characterised as "an interesting and ingenious memoir" by the late Prof. Sohncke, who expressed the hope that his own criticisms (p. 383) would induce the author "to establish his theory in a more solid and more general way." Since that date Mr. Barlow has published several investigations on the subject, and the present memoir, which appears in the scientific *Proceedings* of the Royal Dublin Society, is an extended study of the close-packing of spheres of different sizes. In the arrangement and re-arrangement of such stacks he ingeniously traces a number of interesting analogies which lead him far beyond the features of mere crystalline growth and structure into chemical combination and decomposition, solution, diffusion, and the phenomena classed under stereo-chemistry.

Mr. Barlow himself regards the close packing of spheres as representing the position of equilibrium of mutually repellent particles, and this he believes to be the key to all the problems considered; but the reader must be referred to the original memoir for the details.

The study of crystalline structure as represented by the close packing of spheres or other figures is now being prosecuted by several investigators in very different ways, and with very different interpretations. The geometry of the subject is, of course, independent of all the speculations which gather round it, and deserves the very serious attention of chemists and physicists.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. Oldham, the University Lecturer in Geography, announces a public lecture on the North-west Frontier of India. Sir George Robertson, K.C.S.I., of Chitral fame, will take the chair.

The late Mr. Frank Chance has bequeathed 400 volumes to the University Library.

The Museums Syndicate report that owing to the increase of the number of buildings under their charge, and the greater requirements for research and other students, the sum placed at their disposal for the annual maintenance of the scientific departments must be augmented by 300*l*.

A proposal is made by the Local Lectures Syndicate for the granting of a diploma in Arts to University Extension students who have passed through a prescribed course of study and examinations.

DR. GOTTLIEB, assistant professor of pharmacology in the University of Heidelberg, has been provisionally appointed successor to the late Prof. Dr. W. von Schroeder.

MR. A. E. BRISCOE has been appointed Principal of the new technical institute in course of erection at Stratford. Mr. Briscoe is at present head of the Physics and Electrical Department of the Battersea Polytechnic.

REFERRING to the London University Commission Bill, 1898, which was introduced into the House of Lords by the Lord President of the Council on February 21, and read a first time, the *British Medical Journal* points out that it differs from the Bill of 1897 in the omission of the names of the Commissioners. From the schedule appended to the Bill it appears that the constitution of the Senate is modified by giving to the Council of the City and Guilds of London Institute one member, and by reducing the number of Crown nominees from five to four. The number of members of the Senate is thus retained at the same figure, fifty-five, or with the Chancellor, fifty six. In the paragraph dealing with Faculties, the sub-section recognising examiners appointed by the University as members of the Faculties has been omitted. The instructions to the Commissioners as to examinations are practically the same, and the Senate will be required to hold separate examinations for internal and external students unless it otherwise determine, "either generally by regulation, or as to a particular subject by order." But there is this rather important addition, that the Senate will be required to communicate any such regulation to Convocation. Part II. of the Schedule is now headed, "Matters for which provision must be made." These include the adequate protection of all classes of students whether external or internal, collegiate or non-collegiate, the recognition of teachers of the University, and the regulations for the admission of internal students. The sub-clause dealing with this last point has been modified, and as it nows reads persons to be recognised as internal students will be "students who have matriculated at the University, and are pursuing a course of study approved by the University under one or more of the recognised teachers of the University."

THE official report of the *Proceedings* of the recent annual general meeting of the Association of Technical Institutions, containing the address delivered by the President, the Right Hon. Sir Bernhard Samuelson, Bart., F.R.S., has been issued. In the course of his remarks the President pointed out that much good will arise from the concordance between the various educational agencies which has been arrived at in ten or twelve county boroughs, one of the most conspicuous examples of which is Manchester, where the School Board, the City authorities with their splendid technical schools, and the Owens College of the Victoria University are all acting in harmony, and constructing the ladder so much talked of, but still so rarely provided, on which a child can by intelligence and perseverance mount from the humblest to the highest intellectual position. As to the expenditure of the funds available for technical instruction. Sir Bernhard Samuelson presented the following questions to his audience:—Have we fully considered the relative value of the various degrees of technical education; would it have been better for the nation if the 800,000*l*. per annum of Customs and Excise Fund had been in the main devoted to the higher rather than to the primary and secondary grades of technical education? Would not the lower grades even have been better served if we had in the first instance made a determined effort to extend and improve general elementary and secondary education? Many educationists would answer these questions in the affirmative.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 3.—"Researches in Vortex Motion. Part III. On Spiral or Gyrostatic Vortex Aggregates." By W. M. Hicks, F.R.S.

The chief part of the paper refers to a kind of gyrostatic aggregate. The investigation has brought to light an entirely new system of spiral vortices.

---

[1] "Das Problem der Krystallisation." By A. Turner. Pp. 98; 26 plates. (Leipzig: 1897.)

"A Mechanical Cause of Homogeneity of Structure and Symmetry geometrically investigated; with special application to Crystals and to Chemical Combination." By W. Barlow. Pp. 164. (Dublin: 1897.)

The general conditions for the existence of such systems are determined, and are worked out in more detail for a particular case of spherical aggregate. It is found that the motion in meridian planes is determined from a certain function ψ in the usual manner. The velocity along a parallel of latitude is given by $v = f(\psi)/\rho$ where ρ is the distance of the point from the straight or polar axis. The function ψ satisfies an equation of the form (when expressed in polar coordinates)

$$\frac{d^2\psi}{dr^2} + \frac{1}{r^2}\frac{d^2\psi}{d\theta^2} - \frac{\cot\theta}{r^2}\frac{d\psi}{d\theta} = \rho^2 F - f\frac{df}{d\psi},$$

where F and f are both functions of ψ. The case F uniform and $f \propto \psi$ is treated more fully. If $f = \lambda\psi/a$ where a is the radius of the aggregate,

$$\psi = A\left\{ J_2\left(\frac{\lambda r}{a}\right) - \frac{r^2}{a^2}J(\lambda) \right\} \sin^2\theta.$$

The most striking and remarkable fact brought out is that as λ increases we get a periodic system of families of aggregates. The members of each family differ from one another in the number of layers and equatorial axes they possess. According to the number of independent axes they are called singlets, doublets, triplets, &c., in contradistinction to more or less fortuitous or arbitrary compounds of the former which are considered later and called monads, dyads, triads, &c. Of these families two are investigated more in detail than the others, both because they are specially interesting in their properties and because they serve as limiting cases between the different series. In one family (the λ_2 family) all the members remain at rest in the surrounding fluid. In the other (the λ_1 family) a distinguishing feature, common to all the members, is that the stream lines and the vortex lines are coincident.

The parameter λ gives the total angular pitch of the stream lines on the outer current sheet. The first aggregates—with $\lambda = 5{\cdot}7637$ (the first λ_2 value)—behave abnormally. Beyond these we get successive series, in one set of which the velocity of translation is in the same direction as the polar motion of the central nucleus, in the alternate set the velocity is opposite, and the aggregate regredes in the fluid as compared with its central aggregate.

At the end of the paper a theory of compound aggregates is developed. It is not worked out in detail in the present communication, but the conditions are determined for dyad compounds, whilst a similar theory holds for triad and higher ones. Each element of a poly-ad may consist of singlets, doublets, &c. The equations of condition allow three quantities arbitrary—as for instance ratio of volumes, ratio of primary cyclic constants, and ratio of secondary cyclic constants.

At the end of the abstract, illustrations of the relations of the theory to the vortex cell theory of the ether, and to the periodic law of the chemical elements are touched upon.

February 10.—"The Development and Morphology of the Vascular System in Mammals. The Posterior End of the Aorta and the Iliac Arteries." By Alfred H. Young, M.B., F.R.C.S., and Arthur Robinson, M.D.

Though numerous observations have been made on the development of the systemic aorta and on the aortic arches, including their modifications and transformations at the head end of the embryo, but little attention has hitherto been given to the development and modifications of the primitive vessels and the aortic arches at the caudal end.

The view that the primitive aortæ are prolonged backwards from the dorsal region into the tail, and that, fusing there, they form a caudal aorta—the middle sacral artery—seems to be generally accepted by embryologists. The iliac arteries are accordingly regarded as segmental vessels.

Observations on the development of the posterior end of the aorta and its terminal branches in mammals point, however, to very different conclusions.

The primitive aortæ are not directly continued into the middle sacral artery, but into primary caudal arches, one on each side, the ventral continuations of which either fuse together to form a common vitello-allantoic stem, as in rodents, or they remain separate and form the ventral parts of the allantoic arteries, as in carnivores, ruminants and man.

The middle parts of the primary caudal arches disappear and are replaced by "secondary" caudal arches which lie to the outer sides of the Wolffian ducts. In rodents and man the secondary arches are transformed into the common and internal iliac arteries and the dorsal parts of the hypogastric arteries, whilst in carnivores they are probably transformed into the posterior part of the adult aorta and into the internal iliacs and dorsal parts of the hypogastric arteries.

The vessels, which are to be looked upon as the posterior continuations of the primitive aorta in the adult in man, rodents, &c., are the common iliac, internal iliac, and hypogastric arteries, and in carnivores, &c., the internal iliac and hypogastric arteries.

The common and internal iliac arteries are not segmental vessels, their branches may be.

The middle sacral artery is a secondary branch, probably representing fused segmental vessels.

The permanent adult aorta, in so far as it is formed by the primitive dorsal aortæ, ends posteriorly either at the bifurcation into the two common iliac arteries or at a point corresponding to this bifurcation, when by more extensive fusion involving the dorsal parts of the secondary arches there are no common iliacs, and the external and internal iliac arteries appear to arise directly and separately from the aortæ. In each case the continuity of the primitive aorta is interrupted; the primary caudal arches are replaced by secondary caudal arches, after which the continuations of the aorta are represented by the vessels into which the secondary caudal arches are ultimately transformed.

These conclusions are further supported by more extended observations on the anatomy of the posterior end of the aorta, and its terminal branches in mammals, and on the abnormalities they present in man.

"Further Observations upon the Comparative Chemistry of the Suprarenal Capsules, with Remarks upon the Non-existence of Suprarenal Medulla in Teleostean Fishes." By B. Moore, M.A., and Swale Vincent, M.B.

In a previous communication these authors have shown that the paired segmental suprarenals of Elasmobranchs contain a chromogen giving the same reactions as that of the medullary portion of the suprarenal capsule of higher vertebrates, while the inter-renal body in the same order of fishes contains no such chromogen.

Now the suprarenal bodies of Teleosts do not contain the physiologically active principle which is characteristic of suprarenal medulla, and the natural conclusion would seem to be that, the representative of the medulla is absent. But further evidence is desirable.

A decoction from the suprarenal bodies of *Gadus morrhua* and *Anguilla anguilla* was carefully tested for the chromogen, with entirely negative results. The lymphoid "head-kidney" was also tested, as well as other portions of the kidney, but no trace of the chromogen was found.

From these observations, combined with those previously made, the authors are forced to the conclusion that *the medullary portion of the suprarenal capsules is non-existent in Teleostean fishes.*

"The Effects of Extirpation of the Suprarenal Bodies of the Eel (*Anguilla anguilla*)." By Swale Vincent, M.B.

Teleostean fishes, having only suprarenal cortex, seemed to offer an admirable opportunity of testing how far these "cortical glands" were essential to the life of the animal. Accordingly, a series of extirpation experiments were performed upon the eel.

In three cases in which the animals survived the operation, they appeared quite lively soon after being put back in the tank. One survived twenty-eight days, another sixty-four days, and a third was killed on the 119th day. These experiments show that an eel will survive the operation of extirpation for a very much longer time than mammals or frogs; and the difference is so striking that one must attribute it to the absence of medulla in Teleosts, and must assume that *the cortical gland is not absolutely essential to the life of the animal.* The longest time that a frog will survive removal of its capsules is twelve or thirteen days. Mammals usually die in a day or two.

The validity of these experiments depends upon the actual removal of all suprarenal. This was verified in two ways. (1) Previous study showed that the bodies in the eel are never more than two. (2) All three eels were dissected *post-mortem*, and no trace of suprarenal was found left behind.

Chemical Society, February 17.—Prof. Dewar, President, in the chair.—It was announced that the following changes in the Officers and Council were proposed by the Council. As

Vice-Presidents, Profs. Liveing and J. M. Thomson, *vice* Mr. L. Mond and Prof. Roberts-Austen; as Hon. Secretary, Dr. W. P. Wynne, *vice* Prof. J. M. Thomson; as ordinary Members of Council, Messrs. E. J. Bevan, H. J. Fenton, W. Gowland and D. Howard, *vice* Messrs. B. H. Brough, J. W. Rodger, T. K. Rose, and Prof. S. Young. The following papers were read:—Observations on the influence of the silent discharge of electricity on common air, by W. A. Shenstone and W. T. Evans. Air, when exposed to the action of the silent discharge, first contracts considerably and then expands to nearly its original volume; this is thus explained. Up to a certain stage in the ozonisation of atmospheric oxygen, no nitric peroxide is formed, but after this point is reached, nitric peroxide is produced, and ozone is rapidly decomposed by the silent discharge in presence of nitric peroxide, which is itself at the same time destroyed.—Some lecture experiments, by J. T. Cundall. The author describes lecture experiments illustrating the laws of conservation of mass and of gaseous diffusion.—Note on the preparation and properties of *o*-chlorobromobenzene, by J. J. Dobbie and F. Marsden. Orthochlorobromobenzene is a straw-coloured liquid boiling at 204° under 765 mm. pressure.—The ultra-violet absorption spectra of some closed chain carbon compounds, by W. N. Hartley and J. J. Dobbie. The absorption of ultra-violet rays by diketohexamethylene, pyrrol, thiophene, furfurane, furfurol, pyromucic acid and furfuramide has been examined; the absorption is in some cases very intense, but no absorption bands indicating selective absorption are observed. Note on the absorption bands in the spectrum of benzene, by W. N. Hartley and J. J. Dobbie.—A chemical examination of the constituents of Indian and American podophyllum, by W. R. Dunstan and T. A. Henry. The constituents of Indian podophyllum (*Podophyllum emodi*) and of American podophyllum (*P. peltatum*) are identical; the chief constituent is podophyllotoxin, $C_{15}H_{14}O_6$; the latter on hydration yields podophyllic acid $C_{15}H_{16}O_7$, which forms a lactone, picropodophyllin, which is probably the hydroxycarboxylic acid of dimethoxymethylphenyl-hydro-γ-pyrone. An uncrystallisable resin, podophylloresin, was also isolated.—The volatile constituents of the wood of *Goupia tomentosa*, by W. R. Dunstan and T. A. Henry.—On oxycannabin from Indian hemp, by W. R. Dunstan and T. A. Henry.—On the condensation of formaldehyde with ethylic malonate and on *cis*- and *trans*- tetramethylenedicarboxylic acids (1:3), by E. W. Haworth and W. H. Perkin, jun. The condensation of formaldehyde with ethylic malonate in presence of acetic anhydride yields, in addition to ethylic propanetetracarboxylate, ethylic methylenemalonate and ethylic tetramethylenetetracarboxylate; one of the fractions on hydrolysis and elimination of carbon dioxide yields hexahydrotrimesic acid.—Formation of ethylic dihydroxydinicotinate from ethylic cyanacetate, by S. Ruhemann and K. C. Browning.

Linnean Society, February 3.—Dr. A. Günther, F.R.S., President, in the chair.—Prof. Stewart, F.R.S., exhibited (1) specimens illustrative of the articulation between the upper and lower jaw of a Skate, *Raia batis*, Linn., upon which remarks were made by Prof. Howes and Mr. Holt; and (2) sections of *Puccinia graminis* showing the form of the teleutospores and æcidiospores, upon which some observations were made by Dr. D. H. Scott, F.R.S., confirmatory of the exhibitor's views.—Mr. Thomas Christy exhibited a portion of an iron chain through the links of which a Virginian Creeper had grown, and had become naturally intertwined.—Mr. G. C. Crick read a paper on the muscular attachment of the animal to its shell in some fossil Cephalopoda (*Ammonoidea*). Having first briefly noticed previous descriptions and figures of what were believed to be impressions of the muscular attachment of the Ammonoid animal to its shell, the author pointed out the form and position of the "shell-muscles" and of the "annulus" in the recent *Nautilus*, and indicated the form of the impression of these structures as seen upon an artificial internal cast of its body-chamber for comparison with the fossil forms, in nearly all of which any indication of the muscular attachment there may be is similarly preserved upon the internal cast of that chamber. Dr. H. Woodward, F.R.S., and Mr. B. B. Woodward offered some critical remarks.—Mr. W. C. Worsdell read a paper on the comparative anatomy of certain genera of the *Cycadaceæ*. In conclusion the author endeavoured to show that certain characters in the vegetative structure of these plants showed them to be nearly allied to, or descended from, certain fossil fern-like plants, notably the Medulloseæ, and these characters were: the extrafascicular zones in the stem of *Cycas*, which really represent the outer portion of the flattened concentric strands in the stem of the Medulloseæ, the inner portion of which has died out; and various concentric structures mentioned in the paper. For the type of structure prevailing in the ancestors of the Cycads would have been the concentric, whereas in their descendants it is the collateral. The significant outcome of this study is to form, in the vegetative characters of these plants, a connecting-link, over and above that already afforded by the discovery of spermatozoids in *Cycas* and *Ginkgo*, between "flowering" and "flowerless" plants. Dr. D. H. Scott, F.R.S., in criticising the paper, referred to the importance of certain facts which had been elucidated by the author and which he himself was able to confirm.

Anthropological Institute, February 22.—Mr. F. W. Rudler, President, in the chair.—The Rev. H. N. Hutchinson was elected a member.—Mr. Edge Partington exhibited representations of two tattooed Maori heads, carved in Kawrie resin.—Mr. Cantrill, of the Geological Survey, exhibited a collection of objects, including a delicately-worked flint dagger or knife, obtained during his recent exploration of a cairn in Breconshire.—The Rev. Archibald E. Hunt, of the London Missionary Society, read a paper on the natives of the Murray Islands in Torres Strait, with whom he had lived for three years. His studies had been directed along the lines indicated by the volume of ethnological notes and queries issued by the Anthropological Institute.—Prof. A. C. Haddon exhibited and explained a large series of lantern slides illustrative of the natives described by Mr. Hunt.

CAMBRIDGE.

Philosophical Society, February 7.—Mr. F. Darwin, President, in the chair.—Some zoological results of an expedition to Melanesia during the years 1894–97 (illustrated with photographic slides), by Dr. A. Willey, the Balfour Student. The paper dealt chiefly with observations relating to *Nautilus*, *Ctenoplana*, *Heteroplana*, *Amphioxus*, *Balanoglossus* and *Peripatus*. An account was given of the habits, distribution, and oviposition of *Nautilus*. The function of the tentacular appendages of *Nautilus*, the ciliation of the osphradia or branchial sense-organs and of the accessory olfactory (pre-ocular and post-ocular) tentacles, and the distribution of the pallial, siphuncular, and genital arteries were described. In the metameric system of *Nautilus*, where there are indications of two segments, at least twelve paired structures are repeated. The sheathed tentacular appendages of *Nautilus* and the arms of Dibranchiata are probably to be regarded as pedal in nature and origin, not only on account of their function, innervation and development (Dibranchiata), but also from a general consideration of the phenomena of cephalisation. The "cephalopodium" of *Nautilus* and the Dibranchiata was contrasted with the cephalothorax of Arthropods. *Ctenoplana* is probably to be estimated as a morphological type hardly second in importance to such forms as *Amphioxus*, *Balanoglossus*, *Peripatus*, &c. It presents a transition from biradial to bilateral symmetry. Its pinnate tentacles, like those of the Ctenophora, lie in what corresponds to the sagittal plane of the bilaterally symmetrical Plathelminthes, and are therefore not homologous with the sensory nuchal tentacles of Polyclades as was suggested by Lang. The latter structures are represented in *Ctenoplana* by the aboral ciliated sensory tentacles which are paired about the axis along which the pinnate tentacles lie; and in the Ctenophora by the arcuate sensory ridges and papillæ (Beroidæ) known as the polar plates, which are similarly placed with regard to the aboral sense-organ. *Heteroplana* was described as an anomalous Plathelminth in which the structures of the left side of the body are aborted. This condition appears to be normal for the animal, and not a phase in regeneration. *Amphioxus* was referred to in connection with the discovery of the West Indian subgenus *Asymmetron* Andrews in New Guinea waters, and also at Lifu (Loyalty Islands). The author's view that *Ptychodera* was a relatively primitive type of *Balanoglossus* was confirmed by the structure of his new genus *Spengelia*, which is a *Glandiceps*-like form possessing synapticula or cross-bars in the walls of the branchial sac, medial gonads, and vestigial roots arising from the collar nerve-cord. A new *Peripatus* found in New Britain was described. This form differs essentially from the groups which comprise respectively the Neotropical, Australasian and Cape species of *Peripatus*, and in some respects it is intermediate between the Australasian and Neotropical types.

MANCHESTER.

Literary and Philosophical Society, February 22.—Mr. J. Cosmo Melvill, President, in the chair.—The President announced that Prof. Michael Foster, F.R.S., would deliver the Wilde Lecture before the Society on March 29.—Mr. Melvill exhibited an interesting series of distortions and hyperstrophical deformities of *Planorbis spirorbis*, L., found by Mr. Arthur Stubbs at Black Rock, Tenby. These distortions included (1) evolute whorls, (2) various forms of carination, (3) sinistral turbinate spirals, and (4) dextral turbinate spirals. The causes for such malformations are at present practically unknown, but may be traced to the obstructions to the active but tender-shelled mollusc caused by duckweed and conferva.

DUBLIN.

Royal Dublin Society, January 19.—The Right Rev. Monsignor Molloy in the chair.—Prof. Thomas Preston gave an account of some further observations which he had made in studying the influence of a strong magnetic field on the spectrum of a source of light placed in it. He exhibited photographs by lantern projection, which illustrated the different types of effect, showing that doublets, quartets and sextets are produced, as well as triplets when the source of light is viewed *across* the lines of force. The consideration of these modifications of the normal triplet type was entered into, and it was shown how such modifications could be produced by various forms of reversal accompanying absorption in the vapour of the spark which was the source of light. The connection of these modifications with the complexity of structure of some of the spectral lines, as observed by Michelson, was also passed in review, as well as further matters concerning the influence of the field itself on the molecules.—A paper, consisting of notes on certain Actiniaria (including *Phellia Sollasi*, Haddon) by Dr. Katherine Maguire, was communicated by Prof. A. C. Haddon, who also exhibited a phonograph, cinematograph, and other apparatus to be used in his projected expedition to New Guinea and Borneo.

EDINBURGH.

Mathematical Society, February 11.—Mr. J. B. Clark, President, in the chair.—Mr. Duthie read a paper on a geometrical problem, by S. Guimarães.—A proposal that, in the teaching of elementary geometry, Euclid's definition of proportion be abandoned, was introduced by Prof. Gibson and Mr. W. J. Macdonald, and discussed by several of the members present.

PARIS.

Academy of Sciences, February 21.—M. Wolf in the chair.—Chemical actions exerted by the silent discharge, by M. Berthelot. A preliminary account of the methods employed and general results obtained in the exposure of various mixtures to the action of the silent discharge. In all, more than a hundred and twenty systems were studied, the products being examined at various stages of each reaction.—Chemical actions caused by the silent discharge upon organic compounds. Gaseous systems. Hydrocarbons and nitrogen, by M. Berthelot. The action of the discharge upon the pure hydrocarbons was first studied. Marsh gas gave at first a little acetylene, which afterwards disappeared. After twenty-four hours the remaining gas was practically hydrogen, only five per cent. of the methane being unchanged. With nitrogen, absorption takes place with the formation of basic substances. Detailed results are also given for ethane, ethylene, acetylene, prophylene, trimethylene, and allylene, both alone and mixed with nitrogen.—On derivatives of cinchonine, by M. E. Grimaux. Several derivatives are described of the brominated substance obtained by adding bromine to the crude oxidation product of cinchonine according to the method of Kœnigs and Comstock.—On the place of the sponges in classification, and on the signification attributed to the embryonic leaflets, by M. Edmond Perrier. A criticism of a note on the same subject by M. Delage.—On iteration, by M. C. Bourlet.—Remarks on a note by M. Moreau on cycles of magnetic torsion and the residual torsion of soft iron, by M. H. Bouasse. The two laws announced by M. Moreau on residual torsion can be easily deduced from known facts.—On an analogy between the action of luminous rays and of lines of magnetic force, by M. Birkeland. A Crookes' tube is placed above an electromagnet, and is so arranged that the distance of the kathode from the magnet can be exactly regulated. Beyond a certain distance, the discharge in the tube is uninfluenced by the magnet, but as the tube gradually approaches there is a certain critical position at which all the properties of the discharge are suddenly changed, the difference of potential between the kathode and anode being reduced to a tenth of the original value, and the kathode rays are replaced by others which produce no phosphorescence in the tube. The critical distance increases with the strength of the magnetising current.—On the preponderance of the mechanical action of convection currents in the production of effluvia figures upon fogged plates submitted to the action of thermic poles in developing baths, by M. A. Guébhard.—On a combination of phosphoric anhydride with benzene, by M. H. Giran. The compound described is obtained by heating the two substances in a sealed tube at 120°. It is decomposed by water, and appears to be $C_6H_6 + 4P_2O_5$.—Influence of the X-rays upon the phenomenon of osmosis, by M. H. Bordier. The experiments show that in spite of the interposition of an aluminium plate in communication with the ground, osmosis is much slower when the apparatus is exposed to the X-rays.—Production of a mucinoid substance by bacteria, by MM. A. Charrin and A. Desgrez. A substance of an albuminoid nature is produced by the growth of the pyocyanic bacillus in beef broth. This possesses poisonous properties, a dose 0·15 grams per kilogram proving rapidly fatal to a rabbit. Other bacilli behave similarly.—On bitterness in wines, by MM. J. Bordas, Joulin, and Rackowski. A ferment has been isolated, to which the production of the bitterness in wine appears to be due.—On the aptitude of the spores of the truffle to germinate, and on the function of the aroma, by M. A. de Gramont de Lesparre. The aroma assists in the preservation of the species by its antiseptic action upon the spores.—On ktypeite, a new form of calcium carbonate, differing from both calcite and arragonite, by M. A. Lacroix.—The new form is found in the crystalline deposits of the thermal springs of Carlsbad and Hammam-Meskoutine. Heat transforms the mineral into calcite, with detonation.—Semolina and foods resembling vermicelli or macaroni, by M. Ballard. Analyses of semolina and macaroni from various sources. The quality appears to be in proportion to the amount of nitrogenous material.

NEW SOUTH WALES.

Royal Society, December 1, 1897.—The President, Henry Deane, in the chair.—On the steady flow of water in uniform pipes and channels, by G. H. Knibbs. The paper dealt generally with the nature of the two régimes under which flow takes place, and of the instability of the rectilinear flow in pipes. A general formula was proposed, to express the mean velocity of a flow of water in a circular pipe under either régime, at any temperature, and with any radius, "slope," or material of pipe.—Experimental investigation of the flow of water in uniform channels, by S. H. Barraclough and T. P. Strickland. The main object of this investigation was to fill in an hiatus in the existing series of experimental results, by determining the effect of change of slope upon the velocity of flow, when the slope is varied over a wide range.—Current Papers, No. 3, by H. C. Russell, C.M.G., F.R.S. This paper will be printed in vol. xxxii. of the Society's *Proceedings* for 1898.—Notes on Myrticolorin, by Henry G. Smith. In the abstract of proceedings for August 4, a paper by Mr. Smith is noticed wherein is announced a new dye-stuff obtained from the leaves of the "Red Stringy Bark," *Eucalyptus macrorhyncha*. This material, which in some respects is allied to aromadendrin, was stated to belong to the quercetin group of natural dyes. It was named by the author Myrticolorin, as it was supposed to be the only true dye substance obtained from the Myrtaceæ. This note amplifies previous statements by recording the results arrived at since the announcement above referred to. Myrticolorin is a glucoside of quercetin, and it breaks up on boiling with dilute sulphuric acid into quercetin and a sugar.—A second supplement to a Census of the Fauna of the Older Tertiary of Australia, by Prof. Ralph Tate, with an appendix on Corals, by John Dennant. Prof. Tate begins his paper by giving references to the principal contributions to Australian Tertiary Palæontology which have appeared since the publication of his first supplement in the *Journal* of this Society for 1888. He notes a number of genera hitherto unrecorded as being represented in Australia. In the Polyzoa, a synopsis is given of McGillivray's work, this author being almost entirely responsible for the very large additions to the genera and species of our Eocene fauna. Mr. Dennant's appendix is prefaced by a brief *résumé* of recent work on Australian Tertiary Corals. He then proceeds to record two hitherto unrecorded genera for the Australian Tertiary Corals.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (mathematico-physical section), part 3 (1897), contains the following scientific papers communicated to the Society:—

May 29.—E. Wiechert: The distribution of matter in the interior of the globe.

October 30.—W. Wirtinger: Green's function for a region bounded by non intersecting spherical *continua* of *n* dimensions. K. Hensel: Determination of the discriminants of an algebraical *corpus*. K. Hensel: The fundamental equation and the non-essential discriminant-divisors of an algebraical *corpus*.

November 13.—W. Voigt: Further contributions to the kinetic theory of the process of evaporation.

November 27.—A. Hurwitz: The coefficients of development of the lemniscate-functions. G. Landsberg: On modular systems of the second grade and rings of numbers. O. Wallach: Researches from the Göttingen University Chemical Laboratory—(1) Cisisomerism and transisomerism in the menthol series; (2) ketones ($C_{10}H_{18}O$) from terpinene-nitrite; (3) reduction-products of carvone and eucarvone; (4) a new isomeric camphor from pinene; (5) on pulegenic acid; (6) new compounds from methylhexanone; (7) on fenchone-derivatives.

The official section, part 2 (1897), gives the text of an anniversary address by Dr. F. Merkel, on "the forces which mould the forms of animal bodies," and a report on a journey through Colombia and Venezuela by Prof. O. Bürger.

DIARY OF SOCIETIES.

THURSDAY, MARCH 3.

ROYAL SOCIETY, at 4.30.—The Relationship of Variations of the Ground Water Level to the Incidence of Malarial Fevers in Chotta Nagpur, Bengal: Dr L. Rogers.—On the Depletion of the Endosperm of *Hordeum vulgare* during Germination: H. T. Brown, F.R.S., and F. Escombe.—On Apogamy and the Development of Sporangia upon Fern Prothalli: W. H. Lang and G. A. Clark.—Experimental Observations on the Early Degenerative Changes in the Sensory End Organs of Muscles: Dr. F. E. Batten.

ROYAL INSTITUTION, at 3.—Recent Researches in Magnetism and Diamagnetism: Prof. J. A. Fleming, F.R.S.

LINNEAN SOCIETY, at 8.—On the Sense Organs of the Lateral Line in certain Fishes: F. J. Cole.—On the Occurrence of *Carex helvola* in Britain: G. C. Druce.—On Arctic Spiders from Franz Josef Land: Rev. O. Pickard-Cambridge.

CHEMICAL SOCIETY, at 8.—Note on the Preparation of Dry Hydrogen Cyanide and Carbon Monoxide: John Wade and Lawrence C. Ponting.—Production of some Nitro- and Amido-Oxylutidines: Dr. J. N. Collie, F.R.S., and T. Tickle.—Production of some Nitro- and Amido-Oxylutidines: Dr. J. N. Collie, F.R.S., and Miss L. Hall.—The Interaction of Magnesium and Solution of Copper Sulphate: Dr. E. Divers, F.R.S.

FRIDAY, MARCH 4.

ROYAL INSTITUTION, at 9.—Some Recent Results of Physico-Chemical Inquiry: Prof. T. E. Thorpe, F.R.S.

MONDAY, MARCH 7.

SOCIETY OF ARTS, at 8.—The Principles of Design in Form: Hugh Stannus.

IMPERIAL INSTITUTE, at 8.30.—The Mineral and other Resources of Newfoundland: J. H. Collins.

VICTORIA INSTITUTE, at 4.30.—The Design of the Human Foot: Gerald Smith.

TUESDAY, MARCH 8.

ROYAL INSTITUTION, at 3.—The Simplest Living Things: Prof. E. Ray Lankester, F.R.S.

SOCIETY OF ARTS, at 8.—The Making of a Stained Glass Window: Lewis Foreman Day.

ANTHROPOLOGICAL INSTITUTE, at 8.30.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Papers to be further discussed: *The Theory Design, and Practical Working of Alternate-Current Motors*: Llewelyn B. Atkinson.—Dublin Electric Tramway: H. F. Parshall.—Paper to be read with a view to Discussion: Calcium Carbide and Acetylene: Henry Fowler.

ROYAL HORTICULTURAL SOCIETY.—Floral and Botanical Demonstration.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—*The Passage of a few of the* Salts used in Photography through Gelatine Septa: A. Haddon.

ROYAL VICTORIA HALL, at 8.30.—A Work of Faraday: Prof. Reinold.

WEDNESDAY, MARCH 9.

SOCIETY OF ARTS, at 8.—Linde's Method of producing Extreme Cold and Liquefying Air: Prof. J. Ewing, F.R.S.

GEOLOGICAL SOCIETY, at 8.—Note on Clipperton Atoll: Rear-Admiral Sir W. J. Wharton, K.C.B., F.R.S.—*A Phosphatised Trachyte from Clipperton Atoll*: J. J. H. Teall, F.R.S.—The Pliocene Deposits of the East of England. Part I. The Lenham Beds and the Coralline Crag: F. W. Harmer.

THURSDAY, MARCH 10.

ROYAL SOCIETY, at 4.30.

ROYAL INSTITUTION, at 3.—Recent Researches on Magnetism and Diamagnetism: Prof. J. A. Fleming, F.R.S.

SOCIETY OF ARTS (Indian Section), at 4.30.—India and Sir Henry Maine: Charles Lewis Tupper, C.S.I.

MATHEMATICAL SOCIETY, at 8.—The Geodesic Geometry of Surfaces in non-Euclidean Space: A. N. Whitehead.—The Transformation of Linear Partial Differential Operators by Extended Linear Continuous Groups: Prof. E. Elliott, F.R.S.—Stereographic Illustrations of Catenaries: Prof. Greenhill, F.R.S., and T. I. Dewar.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—On the Manufacture of Lamps and other Apparatus for 200 volt Circuits: G. Binswanger-Byng.

FRIDAY, MARCH 11.

ROYAL INSTITUTION, at 9.—Marked Unexplored: W. F. Lord.

ROYAL ASTRONOMICAL SOCIETY, at 8.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Drainage of Cottage Property: H. C. Adams.

MALACOLOGICAL SOCIETY, at 8.

BOOKS, PAMPHLET, and SERIALS RECEIVED.

BOOKS.—General Report on Public Instruction in the North-West Provinces and Oudh, 1896-97 (Allahabad).—Who's Who, 1898 (Black).—First Year of Scientific Knowledge: P. Bert, revised edition (Relfe).—The Wealth and Progress of New South Wales, 1895-96: T. A. Coghlan, Vol. 2 (Sydney, Gullick).—Das Weltgebäude: Dr. M. W. Meyer (Leipzig, Bibliographisches Institut).—*Universal Electrical Directory, 1898* (Alabaster).—The Miner's Arithmetic and Mensuration: H. Davies (Chapman).—A Sketch of the Natural History (Vertebrates) of the British Islands: F. G. Aflalo (Blackwood).—Semitic Influence in Hellenic Mythology: R. Brown, jun. (Williams).—A Description of Minerals of Commercial Value: *D. M. Barringer (Chapman).—Report on the Economic Resources of the* West Indies: Dr. D. Morris (Eyre).—The *Electrician* Electrical Trades' Directory and Handbook for 1898 (*Electrician* Office).—Der Tägliche Wärmeumsatz im Boden und Die Wärmestrahlung Zwischen Himmel und Erde: Dr T. Homén (Leipzig, Engelmann).—The Chemistry of the *Garden: H. H. Cousins (Macmillan).*—Note-Book of Agricultural Facts and Figures for Farmers and Farm-Students: P. McConnell, 6th edition (Lockwood).—Notes from a Diary, 1873-1881: Sir M. E. Grant Duff, 2 Vols. (Murray).—Report of Observations of Injurious Insects and Common Farm Pests: E. A. Ormerod, 21st Report (Simpkin).—Grundzüge der *Geographisch-Morphologischen* Methode der Pflanzensystematik: Dr. R. v. Wettstein (Jena, Fischer). The Naturalist's Directory, 1898 (Gill).

PAMPHLET.—La Teoria dei Raggi Roentgen: Prof. Filippo Re (Palermo, Reber)).

SERIALS.—American Naturalist, January (Boston, Ginn).—Himmel und Erde, *February* (Berlin, Paetel).—Bulletin of the American Mathematical Society. TWO TEXT-BOOKS OF ELEMENTARY GEOMETRY.

Geometry for Beginners. By G. M. Minchin, M.A., F.R.S. Pp. xii + 102. (Oxford: at the Clarendon Press, 1898.)

Euclid's Elements of Geometry, Books I. and II. Edited for the use of Schools, by Charles Smith, M.A., and Sophie Bryant, D.Sc. Pp. viii + 160. (London: Macmillan and Co., Ltd., 1897.)

THE appearance of these two little books shows that practical teachers have not yet agreed upon the best method of teaching elementary geometry. That this should be so is by no means a matter for regret; in the course of the controversy each party learns something from the criticism of the other; examination papers tend to become less stereotyped, and better adapted to test the student's real knowledge of the subject; while an intelligent teacher is more and more able to assert his right of freedom in giving geometrical instruction according to the method which, after a fair trial, he finds to be most efficient.

Prof. Minchin's book is a very favourable specimen of the methods of the reforming party. It is really what it professes to be, a book for beginners; it is obviously the result of long experience, and there is no reason to be surprised at the author's statement that the book has been used with boys of eight years with very great success. A very welcome feature, which might be adopted by all writers of introductory text-books, is the description of the graduated scale, the compass, the protractor, and set-squares, and of the way in which they are used. Parallel rulers are also described; it would have been well, in our opinion, to add that, while much may be learnt by handling a pair of parallel rulers, they are of little use for practical purposes, and that, generally speaking, set-squares should be used for drawing parallels. It is probably an oversight that the use of set-squares for drawing perpendiculars has not been explained. We thoroughly agree with Prof. Minchin in the opinion that the careful construction of figures, by means of the proper instruments, should be insisted upon for the sake of training the eye and hand of the pupil; and it may be added, that this exercise invariably helps to maintain a boy's interest in the problem or theorem upon which he happens to be engaged.

The choice of propositions is very judicious; they include the congruence of triangles, the elementary theory of parallels, exclusive of the so-called "axiom," properties of parallelograms, easy theorems about areas, and the theorem of Pythagoras. Besides this there are a few miscellaneous propositions, as, for instance, that the angle in a semicircle is a right angle. Definitions, we are glad to see, are introduced when they are wanted, and not before; and when necessary they are clearly explained and illustrated. The exercises are simple and well-chosen: it would be easy to add to their number and variety, and this would be an advantage to the book.

Of course there are some points which provoke criticism; but in offering any remarks upon them it is necessary to bear in mind the intention of the author; thus, for instance, however much the orthodox may protest, we think it is quite legitimate to define a straight line as the shortest distance between two points; on the other hand, it seems to us that the statement "a point is the smallest dot that can be made or imagined" is distinctly misleading, and that it is quite possible to give a more accurate idea of what is meant. Then again there is no objection, at this stage, to saying that a plane is a perfectly flat surface: but the top of a table, a school-slate, or the surface of water in a basin is a better illustration than a sheet of paper. It would also be a good thing to point out the reverse order of procedure, where a surface appears as the boundary of a solid, a line as that of a surface, and a point as that of a line, or the crossing of two lines. A playing ball painted in different colours makes a good illustration; so does a cube, a ruler, or a piece of india-rubber of the ordinary shape.

In some cases only one figure has been given where there ought to have been two or more: for example, in propositions L, S and T; and in the problem on p. 79 it might be pointed out that R may be on either side of PQ, but that the construction fails if we take PR equal to PO, and try to put R on the same side as O.

In cases where circles are used in the construction of figures, it is properly observed that it is not always necessary to draw the complete circles. We would go a little further than this, and in the later propositions, at any rate, introduce in the figures quite small arcs, such as those made by a practical draughtsman; this might be done, for instance, on pp. 78, 79. As the student is supposed to use a pencil compass, there would be four small arcs to indicate on p. 79.

It would be a great mistake to overload a work of this kind; still it might be thought worth while, and would not be inconsistent with the plan of the book, to give the construction for dividing a line into a given number of equal parts, and that for reducing a rectilineal polygon to a rectangle of equal area. The construction of a regular hexagon and a regular octagon might perhaps be included, either as propositions or examples; and it would be well to add some examples, say, of plotting quadrilateral or pentagonal fields from given data, or of drawing such figures as, for instance, a square with an outward semicircle on each side of it as diameter.

These suggestions are made in the confident hope that there will soon be a demand for another edition of Prof. Minchin's excellent little book. In the hands of a competent teacher it cannot fail to be successful; and it will do much, we hope, to convince the average parent and schoolmaster that geometry is not dull mechanical drudgery, and that its principles and results may be comprehended by means of ordinary common-sense. Its adoption as an introductory course will not hinder, but greatly help, a more rigorous study of the subject afterwards; even the most questionable part of the book, the sham proof (for such it is) of the sum of the angles of a triangle being equal to two right angles, need not be a permanent stumbling-block in the pupil's way.

The edition of Euclid's first two books by Mr. C.

Smith and Mrs. Bryant is of the moderately conservative type, preserving Euclid's order of propositions, but admitting, especially in Book II., some simplifications of construction and proof. It is not easy to see any definite advantages of this edition over others already in the market; and in some respects it is certainly inferior. The figures are poor; not a few awkward for the pupil to draw, *e.g.* those on pp. 76, 100; and some are grossly inaccurate, such as those on pp. 80, 122. Then, considering the authors' evident desire for strict logic and accurate statement, some of their *obiter dicta* are really surprising. Thus we are told that "the *unequal* side of an isosceles triangle is generally called the base"; that I. 44 is "sometimes enunciated in the form, 'Construct a parallelogram equal to a given parallelogram, and having one of its sides of given length'"; and that I. 17 is equivalent to "If a straight line intersects two other straight lines which meet in a point, the two interior angles which it makes with those straight lines are together less than two right angles." Not to mention the fact that the three lines may be concurrent, the interior angles referred to ought to have been specified.

The bad plan is followed of placing all the definitions, axioms, and postulates at the beginning; a wrong definition of *postulate* is given so as to confine it to postulates of construction, and the postulate required for the theory of parallels appears in its time-honoured, but non-Euclidean place as an axiom. The authors are of opinion that axiom 9 ("magnitudes which can be made to coincide are equal") is Euclid's definition of the equality of geometrical magnitudes, and ought to be put first, and then the other axioms 1—7 can be proved by superposition. In this we feel sure they are mistaken. The real meaning of axiom 9 is that magnitudes which can be made to coincide are *equal* in a sense consistent with the term as used in the preceding axioms; thus, for instance, if a figure A can be made to coincide with a figure B, and if another figure C can be made to coincide with B, then A and C can be made to coincide. That Euclid does not imply the congruence of equal magnitudes is obvious from I. 35, &c. It is true that either of the parallelograms in I. 35 may be cut up into pieces which may be fitted together so as to make up the other parallelogram; but this fact does not appear in Euclid's proof, and it is doubtful whether he was aware of it. And it is clear that "equal" cannot mean simply "congruent," because if congruent figures are taken from congruent figures the remainders are not necessarily congruent.

This brings us to the statement (p. 66), "Whenever there is equality of area" of two figures, "one of the figures can theoretically be divided into parts which, when properly fitted together, will coincide with the other figure." If "parts" means "a finite number of parts," we should like to know the proof of this assertion: it cannot be true in any sense except for figures drawn upon surfaces which are applicable to each other. To take a very simple case, can it be verified for three circles whose diameters are the sides of a right-angled triangle?[1]

In the alternative proof of II. 12, no reason whatever is given for the equality of the rectangles AY, AZ, so that the whole difficulty of this method of proof is shirked by means of a "similarly" applied to dissimilars; the same imperfection occurs in the alternative proof of II. 13.

In I. 24, figures to illustrate the different cases ought surely to have been given; and we should have thought that the direct proof, by superposition, of the first case of I. 26 might have been admitted as an alternative.

Twenty-six abbreviations have been adopted; the definite article is expressed or omitted according to some mystical principle which we have been unable to discover; in some cases the construction and proof are kept separate, and duly labelled in Clarendon type accordingly, in others they are mixed up.

We confess that, on the whole, the perusal of this book has had a depressing effect; it is like reading a treatise on apologetics, and finding that it leaves you more inclined to be sceptical than before. The most serious objection made against text-books of the more modern type is that young boys fail to really grip the essential parts of some of the proofs, and thus, though they understand them at the time, reproduce them in an imperfect and slipshod manner. But here we have two editors of the orthodox text-book, brought up themselves, no doubt, in the true Euclidean faith, and with scores of school editions from which to take warning and example, who nevertheless are by no means above reproach, in grammar, logic, or precision of statement.

Erroneous methods of teaching elementary geometry are still so prevalent, and teachers are so apt to rely entirely on their text-book, that every treatise, Euclidean or not, which is intended for beginners, should contain a description of simple instruments and their use, and some hints on the proper way of learning the propositions. Before a teacher sets a proposition to be learnt he should, with a class of beginners, go through it with a blackboard explaining every point, and in particular every technical term when it first occurs; he should insist upon the data of the figure, and these only, being first drawn, and the rest put in as the steps of the construction are stated (this should also be done, at first, by the pupil when learning the proposition); and he should, from the outset, avoid using the same letters as those in the book. This, and the early introduction of very simple exercises, will ensure that the pupil uses his brains and not merely his memory; unless this is the case, the study of geometry is about as improving as it would be to learn by heart a page of the London Directory. G. B. M.

OUR BOOK SHELF.

Whittaker's Mechanical Engineer's Pocket-Book. By Philip R. Björling. Pp. 377 + viii. (London: Whittaker and Co., 1898.)

A good pocket-book is a necessity to the engineer; it supplies him with reference tables and constants for facilitating calculations, and also the experience of other engineers in a condensed and handy form for use. One feature of this work is that a rather larger share than usual is given to hydraulics and hydraulic machinery, and also to mining plant. In the formula on p. 3, for the discharge over weirs, a too small coefficient of discharge (apparently 0·45 only) has been adopted; there is also a misprint in the first line of the second column on p. 7, it should be 8·025. In the formula on p. 55, for friction of the leather collars of rams, it is not stated in what units the answer is obtained; presumably it is in pounds. The one section which is very disappointing is that devoted to gas engines; only three pages are given to them, and one of these is filled with a useless description of the two original types—the Lenoir and Otto and Langen, both of course interesting in an historical account of the origin of the gas engine, but not of the slightest value or claim to notice in a pocket-book: in future editions it is to be hoped more attention will be given to this section, and that the page mentioned will be cut out. The author would have done well to make use of the recent determination of the mechanical equivalent of heat; most engineers are now adopting 778 as the figure. On p. 93 occurs an awkward misprint in the formula for mean pressure of steam; the letter in the denominator should be R, and not P, as printed. The rules given for the cooling surface of surface condensers, on p. 113, must apply only to single-cylinder engines; at any rate, they give areas greater than usually adopted in the best modern practice for triple compound plants. The sections devoted to pipes and gearing are admirable, and there are many most useful tables; the last fifty or sixty pages contain a valuable collection of tables of weights of various sections of iron and steel, areas of circles, cubes, square roots, &c. We have pointed out a few blemishes, but the book as a whole is very free from slips or errors, and will be, no doubt, of service to many engineers, draughtsmen, and works-managers. H. B.

---

[1] Unless the arguments of Réthy (*Math. Ann.* xxxviii.) are unsound, this question must be answered in the negative.

Handbooks of Practical Science. No. I. *Mensuration, Hydrostatics and Heat.* Pp. 53. No II. *Chemical Experiments.* Pp. 58. By G. H. Wyatt, B.Sc., A.R.C.Sc. (London: Rivingtons, 1897, 1898.)

Science Handbooks for Laboratory and Class Room: Elementary Physics, Practical and Theoretical. First Year's Course. By John G. Kerr, M.A. Pp. 140. (London: Blackie and Son, 1898.)

Quantitative Practical Chemistry. Part I. Elementary Stage. Pp. 55. Part II. Advanced Stage. Pp. 31. By A. H. Mitchell, B.Sc. (Reading: National Publishing Association, Ltd., 1897.)

A NUMBER of simple and instructive experiments are described by Mr. Wyatt in the practical handbooks referred to above. Following sound educational principles the student is told what to do, but so far as it is practicable he is left to find out for himself the conclusions to be drawn from the experiments. In this respect the books are constructed upon the lines of others which are already in use in schools where elementary science is taught. A few practical exercises are given on the principles brought out by the experiments; but the teacher will find it necessary to considerably increase the number of these, if he wishes his pupils to remember what they have done. In his shorthand manuals Sir Isaac Pitman used to advise the students who wished to become proficient in the art of phonography to "Practice, Practice, Practice," and the same advice applies to instruction in elementary science. Not one or two, but twenty or thirty experiments are, for instance, necessary before young students can thoroughly understand the significance of the principle of Archimedes. The difficulty in the way of carrying out so much experimental work is one of time, and if a large amount of work has to be accomplished in a short time, the depth of knowledge is thinner in proportion to the area covered.

In the first of Mr. Wyatt's handbooks, the usual elementary exercises in mensuration, hydrostatics and heat are given; while the second contains simple experiments on general chemical processes, air, combustion, carbon, various common substances, such as salt, lime, &c., acids, alkalis, hydrogen, water, chalk, and important gases. Too much ground is covered in the latter volume for the work to give satisfactory results, but taken as a whole the handbook will be found very serviceable in teaching the rudiments of science.

Mr. Kerr's book on elementary practical physics has much to commend it, and deserves to be widely adopted by pupils commencing the study of physical science. The book contains about a schoolyear's work of three or four hours per week. In the first half a number of experiments to be performed by the pupils individually are described, and in the second half the chapters are more of a descriptive nature, so that they provide material for the pupil to study and wherewith the teacher may exercise him. The principles of measurement, and simple laws of mechanics, form the subjects of the experiments, and the author has introduced many ingenious methods into his work. The pupil who carries out the experiments will be given knowledge which he is not likely to forget. Moreover, as the experiments are mostly quantitative, they offer a valuable course of training for the mind.

Ability to perform simple quantitative experiments is now required by the Department of Science and Art from students of both the elementary and advanced stages of practical chemistry. The object of Mr. Mitchell's slender volumes is to supplement existing text-books by exercises bearing upon the new requirements. Part I. contains experiments on measurement of length, volume, specific gravity and common chemical changes, and Part II. is concerned with the experiments in volumetric analysis so far as they are required of students in the advanced stage.

Researches on Tuberculosis. The Weber-Parkes Prize Essay, 1897. By Arthur Ransome, M.A., M.D. (Cantab), F.R.S., Consulting Physician to the Manchester Hospital for Consumption, &c.

THE book before us is the reprint of an essay written in accordance with certain specific regulations framed by the Royal College of Physicians. This diminishes to some extent the general value of the book, as it almost confines its contents to the individual experience and results of the author. These latter are, however, very extensive, and almost all ground of interest in this subject is to some extent covered. A lengthy chapter is devoted to the natural history of the tubercle bacillus, another to preventive and prophylactic measures; channels and sources of infection are also fully considered. The book concludes with a chapter upon the direct treatment of phthisis. In this connection it may be mentioned that the author seems to have obtained very satisfactory results from the inhalation of ozone. We are pleased that the Royal College of Physicians gave its consent to the publication of this essay, as the book will no doubt be of considerable interest to those engaged in researches upon this subject. "*The Electrician*" *Electrical Trades' Directory and Handbook for* 1898. (Sixteenth Year). Pp. 918 + cxliii. (London: *The Electrician* Printing and Publishing Co., Ltd., 1898.)

The Universal Electrical Directory (J. A. Berly's). Pp. 1182. (London: H. Alabaster, Gatehouse, and Co., 1898.)

THESE two ponderous volumes give evidence of the remarkable growth of the electrical and allied industries during the past few years. Two large sheets, folded in the first of the volumes at the head of this notice, give particulars of the present electric supply works of the United Kingdom, and the electric railways and tramways. Very few of the supply stations were in existence at the beginning of 1890, and if the progress is as great in the next eight years as it has been in the past eight years, few districts will be without electricity for light, power and traction purposes. The biographical division of the Directory is of more than professional interest, as it contains short sketches of the careers of many physical investigators, accompanied by numerous pleasing portraits. A steel-plate portrait of Mr. J. W. Swann heads this section.

The second Directory contains "a complete record of all the industries directly or indirectly connected with electricity and magnetism, and the names and addresses of manufacturers in Great Britain, India, the Colonies, America, the Continent, &c." Every means has been taken to facilitate reference, and to make the Directory of service to all who are concerned with electrical industries.

A Flower Hunter in Queensland and New Zealand. By Mrs. Rowan. Pp. xiii + 272. (London: Murray, 1898.)

THIS book is one to be laid down with regret, so brightly does the authoress tell of very varied scenes and experiences, and so easily is the reader carried along with her through them. There are few books of travels in which the fascination of the tropics to a naturalist is so evident, or that would more strongly arouse the desire to see for oneself what is here so well described. But the other side of the shield is no less vividly placed before the reader, and the price at which alone the pleasures of tropical travel can be bought can be well realised from it. Old travellers will find their experiences recalled, and will bear witness to the accuracy of Mrs. Rowan's descriptions alike of the beauties and of the discomforts of the tropics, and will recognise that the latter are expressed in no overstrained terms. There are many interesting references to the earlier history of the Colonies, and others, equally interesting, to points in natural history, though in a few of the latter the want of technical knowledge shows itself. Many and wonderful as are the powers of ants, observed in and authenticated from all parts of the world, we should have hesitated to believe about the nests of the green ants of Queensland, that "leaves and flowers are spun together by spiders that the ants keep for the purpose." Mr. Saville-Kent's statement that he has observed the ants use their own full-fed larvæ to supply the silk required for spinning the leaves together, affords an explanation sufficiently curious, but more in accordance with what we should expect. Numerous excellent views add to the attractiveness of the volume. It deserves, and will doubtless receive, a welcome from those interested in travels and natural history.

Introduction to Chemical Methods of Clinical Diagnosis. By D. H. Tappeiner (Munich). Translated from the sixth German edition, with an appendix on micro-biological methods of diagnosis, by Edmond I. McWeeney, M.A., M.D. (Roy. Univ. of Ireland), Professor of Pathology and Bacteriology C.U. Med. Sch., &c. Pp. vii + 152. Figs. 22. (London: Longmans, Green, and Co., 1898.)

THE little book before us consists of two parts—the first, chemical; the second, what the author calls micro-biological. The term micro-biological is an accurate one, and includes the usual bacteriological work on the one hand, and the examination of blood corpuscles and the morphological elements of the secretions on the other. Any system of classification—and one must have some—has its disadvantages: the present one seems to work very well.

The book is well up to date, serum diagnosis and the chemical examination of the gastric contents being contained in it. We think under the chemistry of the urine a method for the quantitative estimation of urea and uric acid ought to have been included. As far as we are aware, there is no book in English of such small bulk which contains so complete an account of chemical and bacteriological or microbiological diagnostic methods. It will not, of course, compete with the larger books on this subject, as, for instance, von Jaksch, but will doubtless have a sale, and deserves it. F. W. T.

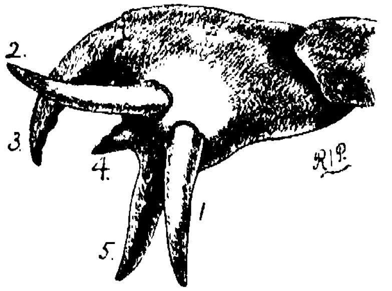
LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Five-fingered Crab.

DURING a recent visit to the museum at Dover, I noticed in the case allotted to the Crustacea a remarkable instance of malformation affecting the right pincer of a half grown specimen of our common edible crab (*Cancer pagurus*); and not recollecting to have seen the like either figured or described, I venture to think the publication of the subjoined sketch, together with a few words of explanation, may prove of interest to the readers of NATURE.

A glance at this sketch will show that there are three complete subequal movable fingers or dactylopodites, numbered 1, 2, 3. Of these, number 3 clearly corresponds to the single movable finger of the normal pincer, numbers 1 and 2 being supernumerary and articulated close together upon an elevation of the hand (propodite), which is much thickened in this region. The two remaining fingers (indices) are immovable. Number 4 is very much the shorter of the two, number 5 being quite comparable in size to either of the three movable digits. Judging from its size and the spot whence it emerges from the hand, the larger index (5) represents the immovable finger of the normal pincer; but its toothed edge is directed, not towards the normal finger (3), but towards the supernumerary finger (1). The smaller index finger (4), on the contrary, has its biting margin turned towards the biting margin of the normal movable finger (3), and in all respects, except size and point of origin, corresponds exactly to the immovable finger of the normal pincer. When the movable digits are closed, number 1 passes on the under side of 5, number 2 on the upper side of 3, and number 3 shuts directly upon 4.



I am only acquainted with records of two cases of malformation in crabs' claws resembling this specimen in the Dover Museum. One of these is figured and described by Mr. Bateson (*Materials for the Study of Variation*, p. 530, No. 815; also *Proc. Zool. Soc.*, 1890, p. 581); the other by M. Sénéchal (*Bull. Soc. Zool. France*, 1888, p. 123). In the former, however, the supernumerary movable fingers numbered 1 and 2 in the figure of the Dover specimen are represented by a single dactylopodite, which, nevertheless, shows its double nature by being divided at the tip and furnished with two rows of teeth along its biting edge. In the example observed by Sénéchal, on the contrary, there are three complete movable digits arranged apparently very much as in the specimen here described and figured; but the process from the propodite (hand) is represented by a broad plate consisting of three only partially separated indices.

February 27. R. I. POCOCK.

Dew and Absorption.

I AM engaged on some daily experiments with a view to measure dew as rain in lineal inches. At present, however, I cannot distinguish between dew and absorption.

I fill a small cylinder (A) of tinned iron—a tobacco canister—to within about 1 inch of the top with garden soil, dry it at 212° F., weigh, expose it over-night, and re-weigh at 9 a.m. before the sun comes on it.

I now purpose to expose another similar tin (B) with ten circular holes pierced near its rim, and covered with a horizontal glass plate.

I hope that B may give some measure of *absorption*, and A—B some measure of *dew*.

I reckon grammes of weight gained as cubic centimetres of water, divide this number by the number of sq. cm. in the circular opening, and take the quotient thus obtained as the measure in linear cm. of dew as rain.

I shall be greatly obliged if any readers can refer me to previous experiments that have been made in this direction.

Harpenden. T. WILSON.

Oat Smut as an Artist's Pigment.

WITH regard to Prof. Marshall Ward's note under this heading (p. 389, *ante*), I may add that, according to Mr. K. Miyabe, the olive-brown spores of *Ustilago esculenta* ("Makomo-zumi" in Japanese), besides its application to the painting of the ladies' eyebrows in Japan, are mixed up with oil and smeared on the scalp and hairs by older women who have the hairs thin or grey. "At present," the author adds, "the spores are largely used in the lacquer industry to produce rusty-coloured wares by mixing them with lac" (*The Botanical Magazine*, Tôkyô, vol. ix. p. 197, May 1895).

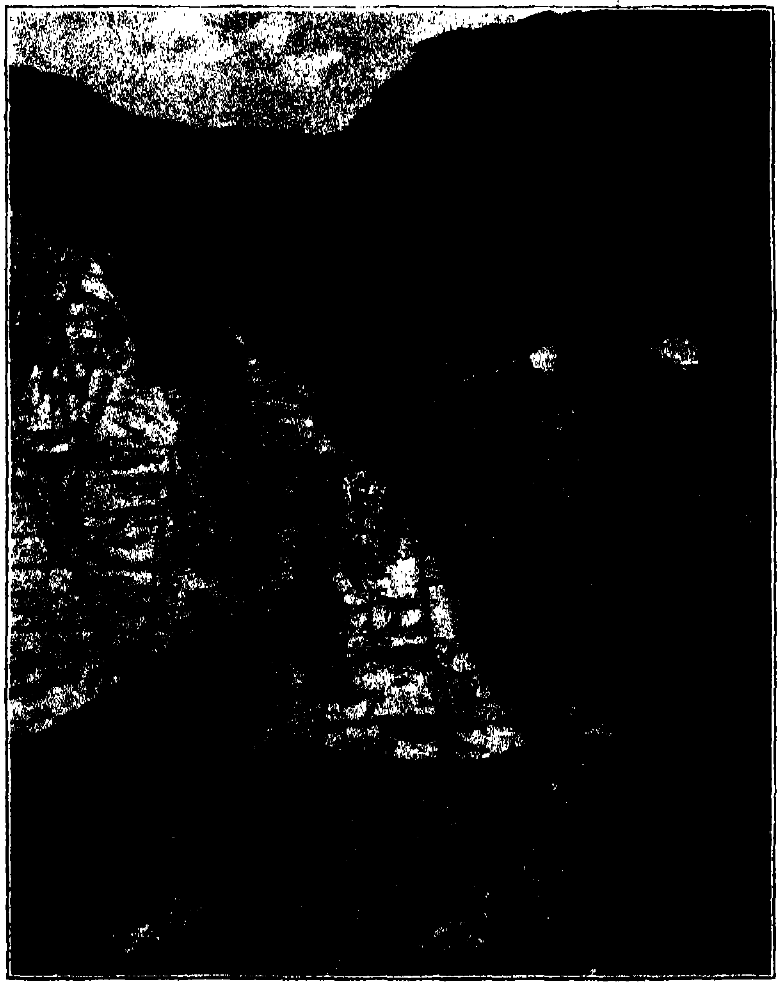
KUMAGUSU MINAKATA.

February 25.

GEOLOGICAL PHOTOGRAPHS.

THE Committee appointed by the British Association for the collection and safeguarding of photographs of geological interest has a good record of work to show for the past year. The entire collection of 1750 prints is now uniformly mounted and deposited in the library of the Museum of Practical Geology at Jermyn Street. Over 350 new prints were received during last year. A new feature has been the formation of a collection of picked duplicates illustrating typical geological phenomena which, in the form of prints or lantern slides, can be lent to local scientific societies or others desiring either to know what work the Committee is doing, or to help on the work.

No less than 119 of the new photographs come from Ireland, and the north of that country is now well illustrated. As is well known, the geology of this region is exceptionally interesting as it was the site of a great volcanic outburst in Tertiary times, and the columnar lavas and sills, the dykes intrusive into chalk and into newer and older rocks, the laccolites, volcanic necks and ash beds, form a text-book of volcanic geology. One of the most remarkable localities is Cave Hill, near Belfast, where the unconformable junction of the chalk with the lavas has been well exposed by the quarrying operations.



[Photographed by Mr. R. Welch, Belfast.] [Copyright.

FIG. 1.—Cave Hill, Belfast.

The remarkable section shown in the annexed figure (Fig. 1) is reproduced from an excellent photograph by Mr. R. Welch, of Belfast. Unfortunately the section is now being destroyed by quarrying, so that this photograph is the best record we possess of it. It shows an old, steep, pre-Tertiary cliff of chalk which was gradually buried in débris, most of which was derived from itself. Both cliff and débris were buried by basaltic lavas and ash beds thrown out by the volcanoes which broke out along great fissures in early Eocene times.

Glacial phenomena admit admirably of registration by photography, and the collection is fairly rich in such illustrations.

Although Ramsay many years ago wrote an account of the glaciation of North Wales, comparatively little connected work has been since done to elucidate this remarkable example of upland glaciation, while a complete photographic record of it remains to be executed. Some few points have, however, been dealt with, notably by the late J. J. Cole, Messrs. Williamson and Wills, Mr. Godfrey Bingley, Mr. Atchison and others, and their work is in the collection. Good as it is, however, it serves best to show how much in the way of systematic recording there is still left to be done. Some one should set to work with Ramsay's book in his hand, visit the localities mentioned, photograph them, and, guided by it, seek out and record a complete account of the glaciation of the entire region; and he cannot do better than begin on Snowdon. Just opposite Snowdon, on a small hill, Y Foel Perfedd, above Pen-y Pass Hotel, the perched block shown in Mr. Bingley's photograph (Fig. 2), of which a reproduction is annexed, overhangs the Pass of

Llanberis, and looks as if a mere touch would precipitate it into the Pass below.

Photographs have often been taken of single examples of fossil trees in submerged forests and in the coal-measures or other rocks. But it is not often that a whole forest of Carboniferous trees is exposed to-day in quarrying operations, and it is still more rare to have them preserved for future generations by a building, as has been done in the instance from Partick, figured below. This photograph was taken by Mr. R. McF. Mure, of Paisley, who has kindly furnished me with particulars as to the size of the trees: the stems are most of them over two feet in diameter at the base, and the spread of the roots in some cases is correspondingly large.

W. W. WATTS.

SOME RARE BIRDS' EGGS.

ON comparing the numerous works which have appeared of late years on British birds with their predecessors of a couple of decades or more ago, we cannot fail to be struck with the great diminution in the number of species whose eggs and nests are stated to be unknown. And since the appearance of even the more recent of these, one more gap has been filled up by the announcement of the discovery by Mr. Popham, last July, on an island in the mouth of the Yenisei, of the long-sought eggs of the curlew-sandpiper (*Tringa subarquata*). By this fortunate discovery the number of species entitled, even by the utmost stretch of courtesy, to be included in the British list whose eggs still remain unknown, is very small indeed, although there are several species of which the known specimens are extremely few. Of course there are a host of foreign birds whose nidification awaits discovery, but to mention even a portion of these would obviously be impossible within the limits of an ordinary article. The majority of the British species whose breeding haunts offered the longest resistance to the efforts of egg-hunters, were those which migrate at this season to the desolate Arctic tundras; and among the eager explorers of the avifauna of those regions the name of John Wolley will always stand pre-eminent, ably as his pioneer efforts have been seconded and completed by men of the stamp of the late Mr. H. Seebohm and Colonel Feilden, to say nothing of many equally enthusiastic and capable observers. At the present day one of the great fields remaining for exploration are the breeding areas of many of the species inhabiting the southern hemisphere.

In many respects birds' eggs have proved a somewhat disappointing study, since, if we except their aid in bringing about the recognition of the intimate structural affinities existing between the Limicolæ and the Gaviæ, they have afforded comparatively little assistance in unravelling the tangled skein of avian relationships. And many of the generalisations which have been drawn from them, such as those relating to white eggs, have turned out to be true only in part. Moreover, it is unlikely that those remaining to be discovered will add anything really important to our stock of knowledge. The newly-discovered eggs of the curlew-sandpiper, for example, do not differ from those of the allied forms in any more important degree than do the different postage-stamps of the same issue.

Not that the quest of birds' eggs is in any way to be discouraged—far from it. While the eggs themselves, from the intrinsic beauty of their shape and coloration, form a never-ending source of delight to the collector, it is only through the energy of the hunter after these spoils that a knowledge of the habits of the birds themselves can ever be attained. In the words of Prof. A. Newton, it is the field naturalist who alone crowns the labours of the anatomist and the museum-worker. "What engineer," writes the Professor, "can be said to understand his business if he knows not the purpose to which the machines he makes are to be applied, and is unacquainted with their mode of working. We may investigate thoroughly the organs of any animal, we may trace them from the earliest moment in which they become defined, and watch them as they develop to maturity, we may comprehend the way in which every part of a complicated structure is built up; but if we take not the trouble to know their effects on the economy of the creature, we as naturalists have done but half our task, and abandon our labour when the fulness of reward is coming upon us." All honour then to those (if only they work in the right way) who risk their health, if not their lives, and spend their treasure, in the quest of the rarer birds' eggs!

Although they have been removed from the list of desiderata, the eggs of the curlew-sandpiper will probably long remain among the rarest of those of the British species, those from the Yenisei being the only specimens at present known. Among the species included in the British lists whose eggs were unknown at least as late as 1896, is Pallas's grey shrike (*Lanius sibiricus*), but as this bird is so closely allied to the ordinary species, their discovery cannot be looked forward to with any special interest. The second is the needle-tailed swift (*Chætura caudacuta*), which has only twice been seen in Britain, and breeds in northern Asia, although its eggs are still unknown. Equally slight are the claims of the sharp-tailed sandpiper (*Tringa acuminuta*) to be regarded as British; and, although still unknown, its eggs will probably prove very similar to those of the American *T. maculata*. To the rare and beautiful wedge-tailed gull (*Rhodostethia rosea*), reported to have been once seen in Britain, is provisionally assigned a single egg in the British Museum obtained from Disco Bay. Of far more interest would be the discovery of the eggs of the Cape petrel (*Daption capensis*), since this bird, of which an example was killed in Dublin in 1881, represents a genus by itself. One of its breeding-places appears to be Kerguelen Island. Of two other petrels, namely *Œstrelata hæsitata* and *Œ. brevipes*, with equally slight claims to admission in the British lists, the eggs are likewise unknown.

Of species whose eggs are known, although of extreme rarity, next to the curlew-sandpiper, the white-billed diver (*Colymbus adamsi*), a by no means very rare visitor to our coasts, may first claim attention. The only known eggs, which are very like those of the great northern diver, were obtained during the voyage of the *Vega* in 1879. Of the lovely ivory gull (*Pagophila eburnea*) the eggs have been described by Prof. Collett; while those of the Iceland gull (*Larus leucopterus*) and Mediterranean black-backed gull (*L. melanocephalus*) come also under the category of rarities, the nest of the latter species being unknown. Of greater interest are the beautiful eggs of the Sandwich tern, of which additional specimens were recorded last year. Although obtained by Wolley, the eggs of the spotted redshank (*Totanus fuscus*) must be regarded as prizes by the collector; while so late as 1893 those of the solitary sandpiper (*T. solitarius*) were recorded by Mr. Dixon as unknown, although one clutch has been described by Mr. Elliot, in which the eggs resembled those of the piping sand-plover. Claim to a place in this section is undoubtedly held by the sanderling, of which eggs were obtained by MacFarlane in Arctic America in 1863, and subsequently by Colonel Feilden in Grinnell-land. The knot (*Tringa canutus*) is another of the species which appears in Mr. Dixon's book of 1893 as among those of which the eggs are unknown. It seems, however, that a clutch of four was taken in Greenland as far back as 1875, one of which is now in the British Museum; and these, with a single specimen taken from the body of a female by Lieut. Greeley, appear to be the only examples in collections. Far less uncommon are the eggs of the little stint (*T. minuta*), although they still come under the category of rarities, as do those of the jack snipe, which were first taken by Wolley in Lapland. The crestless lapwing (*Vanellus gregarius*), of which but one British specimen is on record, is also a bird of whose nidification details are wanting, although the eggs are known to be four in number, and very similar to those of the crested species. Dotterel eggs, although very handsome, can now scarcely be considered as rarities; but those of the lesser golden plover (*Charadrius dominicus*) are very scarce, although their similarity to those of the ordinary species renders them less interesting than would otherwise be the case.

Passing other members of the foregoing groups whose eggs are more or less scarce, allusion must specially be made to the common bernicle goose, of which it is a remarkable fact that eggs laid in a wild state are quite unknown, although this is somewhat discounted by the circumstance that birds have nested in captivity. Of the nearly allied red-breasted bernicle (*Bernicla ruficollis*) the eggs have, however, been discovered, and, except for their somewhat smaller dimensions, are stated to be indistinguishable from those of the bean-goose.

Although the eggs of all the species of birds of prey recorded as British are known, some are comparatively rare in collections. Among such may be mentioned those of the red-footed kestrel (*Falco vespertinus*), which although not uncommonly taken in Russia, were so poorly represented in the British Museum in 1896 that Dr. Bowdler Sharpe stated he was unable to properly define their characters.

In addition to those of Pallas's shrike, which have already been mentioned in the unknown list, the following are some of the rarer eggs among the British Passerines. From their beautiful markings the eggs of all the buntings are always favourites with collectors; and from their rarity those of the rustic bunting must be specially prized. Two only are in the Seebohm collection in the British Museum, although others have been described by Mr. Dresser, and yet others are mentioned by Prof. Newton as among the specialities of last year's collecting. Richard's pipit (*Anthus richardi*) affords an example of a bird of which the eggs are known, but the nest has never been described. Among comparative rarities the eggs of the yellow-browed willow-warbler (*Phylloscopus superciliaris*) and the marsh-warbler (*Acrocephalus palustris*) deserve passing mention, especially as many referred to the latter species appear to be nothing more than pale examples of the reed-warbler. Perhaps the greatest prizes among the British representatives of the group are, however, the eggs of White's thrush (*Turdus varius*). A nest, with eggs, from Ningpo attributed to this species is included in the Seebohm collection, and undoubted specimens are mentioned in Prof. Newton's list of new acquisitions. Less rare are the eggs of the black-throated ouzel (*T. atrigularis*), of which several clutches have been taken in the Altai, although the nest is still unknown. Another desideratum is the nest of the Siberian ground-thrush (*T. sibiricus*), of the eggs of which three specimens taken in Japan, and now in the Seebohm collection, were the only examples known up to 1896. Of the Arctic bluethroat (*Cyanecula suecica*) the eggs, which resemble those of a redwing in miniature, are far less rare, but must still be reckoned as among the collector's choicest treasures.

To go further into the British list would be beyond the limits of this article, while, as already said, species not occurring in that list must be excluded. An exception may, however, be made in favour of the rare Pander's chough-thrush (*Podoces panderi*), of the deserts of Central

Asia. Of this bird the eggs were first obtained, we believe, by Fedtchenko, and have ever since ranked as great rarities, and collectors will therefore be interested in finding specimens included among those collected last year and mentioned by Prof. Newton. R. L.

NOTES.

THE Council of the Royal Society have invited Dr. Wilhelm Pfeffer, professor of botany in the University of Leipzig, and foreign member of the Royal Society, to deliver the Croonian Lecture on March 17. The subject of the lecture is to be "On the Nature and Significance of Functional Metabolism (*Betriebsstoffwechsels*) in the Plant." The lecture will be delivered in German. Prof. Pfeffer is well known among botanists for his two volumes on "Pflanzenphysiologie," published in 1881 from Tübingen, and the second edition of which was issued last year; while his views on the function of chlorophyll, and its absorption-spectrum, are familiar to workers on the physiology of plant-life.

MORE than 100 foreign zoologists have now consented to be members of the "Committee of Patronage" of the Fourth International Congress of Zoology, and a large number of them have expressed the hope that they will be able to be present at the meeting in August next. Among these we may mention the names of Prof. Häckel, of Jena; Prof. Graff, of Graz; Prof. Grassi, of Rome; M. Blanchard, of Paris; Baron Jules de Guerne, who has been associated with the Prince of Monaco; Dr. Jentink, of Leyden, who was President of the Third Congress; Dr. Dollo, of Brussels; and Prof. Collett, of Christiania. From the United States it is hoped there will be a somewhat large contingent; Profs. Osborn and Scott, Prof. E. B. Wilson, and Mr. Watasé, of Chicago, all hope to be able to come.

THE sixth "James Forrest" Lecture of the Institution of Civil Engineers will be delivered on Thursday, March 17, at eight o'clock. Prof. W. Boyd Dawkins, F.R.S., the lecturer, takes for his subject "Geology in relation to Engineering."

THE Mayor of Bradford presided at a meeting, held on Monday, for the purpose of considering a proposal to invite the British Association to Bradford for the year 1900. It was unanimously decided to send an invitation to the Association for the year 1900, and an executive committee was appointed to make arrangements if the invitation should be accepted.

IT is expected that some of the observers of the recent total eclipse of the sun will give a preliminary account of their observations at the meeting of the Royal Astronomical Society to-morrow.

THE Municipal Council of Paris have inserted in the budget for this year the sum of ten thousand francs, for the laboratory of photography and radiography at the Salpêtrière.

THE following grants have recently been made by the Trustees of the Elizabeth Thompson Science Fund:—250 dollars to Prof. Gustav Hüfner (Tübingen), for the investigation of hæmin and hæmatine; 288 dollars to Prof. Carlo Bonacini (Modena), for researches in colour photography; 250 dollars to Prof. John Milne, to aid in a seismic survey of the world.

THE Zürich correspondent of the *Times* states that the observatory on Mont Blanc, which was constructed by M. Joseph Vallot some seven years ago, is to be transferred to another site. The present structure is built on a small rocky plateau, which extends for a short distance from the Rochers des Bosses, but its position is no longer favourable for scientific observations. The construction of the building has served as a barrier against which the snow piles itself in ever-increasing masses, causing both trouble and expense to the observatory staff. The whole erection is to be transferred, piece by piece, on the backs of workmen from the Rochers des Bosses to a rocky point at the same altitude, where the ground will first be levelled by blasting, and, in spite of the difficulties of climate and transport attending these operations, it is hoped that the whole transfer will be finished in the course of one summer season.

AT the meeting of the Entomological Society of London on March 2, a discussion took place on the reported introduction of the San José scale, *Aspidiotus perniciosus*, into Great Britain. Mr. R. Newstead, the only British entomologist who is now specially occupied with Coccidæ, stated that during the past nine years he had never once met with this species among the numerous scale-insects taken in this country and forwarded to him for identification. It was impossible even for an expert to distinguish it, without careful microscopical preparation and examination, from among the thirty or more described species of *Aspidiotus*, and any attempt to identify it on imported fruit by naked-eye observation, or with a hand-lens, was therefore quite impracticable. The risk of its distribution by importation on fruit was small; there was, however, much more likelihood of its introduction on plants or trees. At the same time he saw no reason to suppose that it would be more injurious in this country than the common *Mytilaspis pomorum*; in America the San José scale had several, sometimes as many as five, generations in the year, but in this climate it would probably conform with the habits of all other scale-insects at present investigated and become single-brooded. Mr. Newstead's conclusions were generally agreed with by the Fellows present.

ACCORDING to the *Bulletin de la Société Française de Physique*, M. Crémieu has devised an ingenious means of producing elliptic sound-vibrations in air. By the interference of the longitudinal vibrations of two organ-pipes, placed at right angles, and vibrating under the influence of two diapasons with the proper difference of phase, an elliptic motion was set up at the intersection of the tubes, and its existence was made evident by means of delicate quartz fibres which followed all the movements of the air.

M. A. LEDUC, in a paper read before the Société Française de Physique, criticises the well-known law of mixture of gases, according to which the pressure of a mixture is the sum of the pressures of its constituents at the same volume and temperature. This law is only true for perfect gases, and is then equivalent to the statement that the volume of the mixture equals the sum of the volumes of its constituents at the same pressure and temperature. From experiments on several gas-mixtures, M. Leduc considers that the second form of the law is rigorously applicable to certain mixtures of real gases, and is, in general, in closer approximation with experiment than the first.

IN the *Annales du Bureau Central Meteorologique*, M. Moureaux gives an account of the different comparisons he has made between the magnetic instruments of the Parc Saint Maur Observatory and those of the observatories at Kew, Uccle (Brussels) and Pavlovsk (St. Petersbourg). The comparison observations made at Kew have already been described by Mr. Chree in a communication to the Royal Society. The declination at Pavlovsk was found to be 1'·3 higher than the French standard, the horizontal force 0·00013 lower, and the dip 0'·8 lower. At Uccle the declination was 1'·5 lower, the horizontal force 0·00002 lower, and the dip was not compared. In the account of the Kew comparisons an arithmetical error occurs which makes the horizontal force difference 0·00011 when it ought to be 0·00012.

IN connection with recent measurements of the temperature of the air at high altitudes, Signor Luigi de Marchi, writing in the *Rendiconto del R. Istituto Lombardo*, discusses the validity of Mendeléef's and Herschel's laws connecting temperature with altitude, and draws conclusions which may be briefly summed up thus:—(*a*) Recent measurements of temperature of the higher strata of the atmosphere can be represented by a formula of the type of Mendeléef's, viz. $t + C = (T + C)p/P$, where, however, C increases with the altitude; (*b*) for altitudes below about 4500 metres the formula agrees with observation when C is taken as a linear function of the altitude, but for greater altitudes, up to 13,000 metres, the supposition that C is a linear function of the pressure gives the best results, the formula then reducing, like Herschel's, to an equation of the second degree in p; (*c*) for altitudes of a few thousand metres Mendeléef's formula gives sufficiently approximate results when C is taken to be constant; (*d*) the validity of the proposed formula, if substantiated by further observations, would confirm the hypothesis that the temperature of a stratum at any given altitude is determined principally by the equilibrium between the thermal radiations which it receives from the ground, and which it emits into the sky, when the assumed law of radiation is that of Newton or of Stefan. The latter law in the strata hitherto reached would lead to a formula less reconcilable with the data of observation than the former.

ONE of the difficulties which water-engineers have to face is the unpleasant odour which sometimes characterises surface waters stored in open reservoirs. Such odours are frequently supposed to be due to the decomposition of organic matter in the water, but, although such may be the case, in many instances they have been found to be attributable to the growth of microscopical organisms, and quite a long list has now been furnished of vegetable growths which impart disagreeable tastes and smells to water. Messrs. Jackson and Ellms have just published a memoir describing their investigations upon one of the *Cyanophyceæ* or blue-green Algæ which, when growing in water, impregnates the latter with a most unpleasant mouldy grassy smell. Pure cultures of *Anabæna circinalis*, an important offender in this particular, were obtained and numerous experiments were carried out. As in the case of other microscopical water-organisms, the odour emitted during growth was found to be due to the presence of certain compounds of the nature of essential oils which make their appearance at a particular stage of growth. The investigation was also extended to an examination of these Anabæna during decay, a most offensive odour being given off during decomposition. This the writers think is probably due to the high percentages of nitrogen which these growths contain. The gas given off during decomposition was analysed and was found to contain a large percentage of hydrogen, and a considerable proportion of sulphur compounds. Analyses of the decayed gelatinous material resulting from the decomposition of Anabæna revealed the presence of a large amount of sulphur and a considerable amount of phosphorus. The subject is of such importance in connection with the storage of surface waters, that the closer study of the chemical composition of these organisms and of the organic and mineral contents of the waters which the various genera infest, is well worthy of attention; for by extending our knowledge in this manner, we should be better able to judge beforehand of the likelihood of particular waters becoming subject to these unpleasant changes on storage. The above memoir is to be found in vol. x. of the *Technology Quarterly*, Massachusetts.

THE receipt by the University of Pennsylvania of a collection of mammalian fossils from the tundra at the back of Point Barrow, Alaska, has induced Mr. S. N. Rhoads to put together the available information on the living and extinct species of North American *Boves*. Mr. Rhoads refers one of the Alaskan Bison-heads to an unnamed species which he proposes to call *Bison alaskensis* (*Proc. Ac. N.S. Phil.*, 1897, p. 490). He has likewise taken this opportunity to examine the question of the so-called "Woodland Bison" of the Peace-River district of Athabasca. It appears that an adult male specimen of this little-known animal has recently been obtained by the Geological Museum of Ottawa. Mr. Rhoads describes this example from information sent to him by Prof. J. Macoun, and refers it to a new sub-species, *Bison bison athabascæ*, separating it from the typical form on account of its "great size, darkness of colour, and the characters of the horns and horn-cores."

AN interesting article on the wild cattle of Chartley, Staffordshire, is contributed to *Nature Notes* by Mr. J. R. B. Masefield. This herd of wild white cattle is of great antiquity; but whether the present animals are directly descended from some one of the ancient native species, such as *Bos primigenius*, *Bos longifrons*, &c., or whether they are descendants of domestic cattle introduced by the Romans and run wild, is still an undecided question. The home of these cattle is situated on high ground some 300 feet above sea-level, and was enclosed about the year 1200, and forms a portion of Chartley Park, some five miles from Uttoxeter, the nearest town. The extent of this wild tract of table-land is about 1000 acres, covered with coarse grass, rushes, stunted bilberries, and heather, and patches of luxuriant bracken fern, with a few clumps of old weather-beaten Scotch firs and birch, which afford some shade from the hot summer sun. Among the other denizens of this wild primeval tract are herds of red and fallow deer and multitudes of rabbits, (with no doubt a few of their natural enemies, the stoat and voles—both the common vole and red bank vole), moles, long-tailed field mice, shrews, weasels, and adders. The theory that the Chartley breed of wild cattle is indigenous appears to be supported by their general habits at the present day. When alarmed they start off at full gallop for a short distance, then turn and face their foe in a semicircle, with the bulls in front, the cows behind, and the younger animals and calves still further in the rear. If closer approached, these tactics, which are clearly those of wild animals, are repeated, or the adversary is charged and attacked. Again, they conceal their young in fern or long rushes, and the cows, when calves are born, become exceedingly fierce and dangerous, especially if an intruder should get between a cow and her calf. Mr. Masefield points out that a fine herd of white cattle, very strongly resembling the Chartley breed, are to be found at Lamphey Court, near Tenby, in South Wales; they are said to belong to an old Welsh breed, but in colour and general appearance it is difficult to distinguish them from the Chartley animals.

M. P. VUILLOT has completed a map of the lake districts of Timbuktu on the scale of 1/100,000, which contains a number of topographical discoveries in this little-known region. In presenting the map to the Paris Geographical Society, M. Vuillot adds an interesting note on the hydrography of the area, and on its productiveness, which has been published in the Society's *Comptes rendus*.

PROF. THEOBALD FISCHER contributes a short paper to *Petermann's Mittheilungen* on the "moraine-amphitheatre" of the Lake of Garda. The form of the moraine deposits on the inner or Italian side of the Alps differs markedly in type from that on the outer or German side. In the former type, of which the Lake of Garda affords an excellent example, the deposits are laid down in concentric ramparts which turn their convex side to the plains; while in the latter we find the familiar expanded fan shape at the mouths of the valleys. Dr. Fischer avails himself of the very excellent maps and models furnished by the Italian Service.

THE first two numbers of the new volume of the *Mittheilungen* of the Vienna Geographical Society are devoted to a memoir on the Hallstätter See, by Dr. Lorenz, Ritter von Liburnau, which extends to over 200 octavo pages. The form and position of the lake are discussed, chemical analyses are given of its waters and of the waters of the inflowing streams, and there are elaborate investigations into the distribution of temperature at different depths and at different seasons, into currents, transparency and colour of water, and the various forms of life. Dr. Lorenz had the assistance of a large number of colleagues in making his observations, and was fortunate in having a steam launch placed at his disposal free of cost.

Petermann's Mittheilungen contains an account of a recent expedition into the interior of Dutch East Borneo by Dr. A. W. Nieuwenhuis. The region between the upper basins of the Kapuas and the Kutei or Mahakam rivers was not visited by the Dutch expedition of 1894, owing to the supposed hostility of the natives; but by judicious treatment and selection of native companions, Dr. Nieuwenhuis has succeeded in exploring a considerable area. A stay of eight months was made at a station on the Bloeoe, a small right-bank tributary of the Mahakam, giving opportunity for detailed topographical and geological surveys. Extensive collections were made, which have reached Buitenzorg in safety.

IN descending the Niger, the Hourst Expedition found the navigation of that river impeded by rapids from Ansongo to below Boussa. As this was during the season of high water, M. le Lieut. de Chevigne was detailed in May 1897 to make a further reconnaissance when the river was at its lowest. The results of his observations are published in the *Comptes rendus* of the Paris Geographical Society, and are described as of special importance on account of a French station having been recently established at Say. The Niger is to be considered as navigable from Timbuktu to Ansongo, but only during high water; below Ansongo, rocky shallows and rapids render navigation difficult at all seasons, and dangerous, if not impossible, for nine months in the year.

IN the *Bulletin* of the Imperial Society of Naturalists of Moscow, No. 2 for 1897, is a lengthy and important paper (in German) by C. Sokolowa, on the growth of root-hairs and rhizoids. He appears to have come to the conclusion that neither the growth of the cell-wall nor the currents in the protoplasm are directly dependent on the cell-nucleus, although the position of the nucleus appears to a certain extent to determine the direction of the currents. N. Malischeff contributes some remarks on the nerve-endings in the œsophagus and stomach of birds. The remaining papers are in Russian.

DR. F. VON KERNER publishes a short account of some recent geological work on the coast regions of Dalmatia in the *Verhandlungen* of the Austrian Geological Survey. The peninsula of Ostrica, the island of Zlarin, and a number of the neighbouring rocky islets were surveyed, disclosing some features of geological and geographical interest. The islands together form part of the submerged lower course of the river Kerka.

AT the recent Ithaca meeting, the Association of American Anatomists adopted the report of the majority of the Committee on Anatomical Nomenclature, and ordered it to be published and distributed as soon as practicable, accompanied by the objections of the minority of the Committee, and comments thereon by the Secretary of the Committee. Of the neural terms recommended, more than 100 were identical with those adopted in 1895 by the Anatomische Gesellschaft.

WITH reference to our note on M. J. Deniker' papers on the characteristics of the inhabitants of the various districts of Europe (p. 351-2), the author writes to correct an error which unfortunately crept into his paper. In our note, p. 352, line 14, the race "(β) Blond, mesocephalic, very short," should be ascribed to Saxony-Poland instead of Sweden.

THE additions to the Zoological Society's Gardens during the past week include a Masked Paradoxure (*Paradoxure larratus*), a Large Indian Civet (*Viverra sibetha*) from Western Szechuen, China, presented by Mr. Julius Newmann; three Punjaub Wild Sheep (*Ovis vignei*, ♂ ♀ ♀) from Southern Persia, deposited; a Common Seal (*Shoca vitulina*) from Holland, an Indian River Snake (*Tropidonotus piscator*) from India, purchased; a Leopard (*Felis pardus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OCCULTATION OF ANTARES.—The occultation of a star of the first magnitude is of rare occurrence, more especially when the moon is at such a favourable age as in the case of the occultation of Antares (α Scorpii) magnitude 1·1, on March 13, when the moon is in the last quarter. The times of disappearance at the bright edge and reappearance at the dark edge, as given in the *Nautical Almanac*, for Greenwich are 14h. 38m. 0s., and 15h. 49m. 0s; and the angles at which these respective phenomena take place are 111° and 305°, measured from the vertex. The occultation of this beautiful red star is a most interesting observation, especially at the favourable phase of the moon, which should render the doubling of Antares easily visible. It was during an occultation that Burg discovered the celebrated blue companion in 1819.

NAUTICAL ALMANAC, 1901.—The *Nautical Almanac* for the year 1901 has just been issued. It is arranged in a similar way to those now familiar to us, and from it we learn the details of the total eclipse of the sun which takes place in that year on May 17. The path of the shadow passes over Sumatra, Borneo, Celebes, and the southern part of New Guinea; the eclipse will also be visible in Australia, but only as a large partial one, whilst in Europe and America no trace of it can be observed. This eclipse is remarkable for being one in which the duration of totality is nearly the longest possible, the maximum obscuration of the sun lasting about six and a half minutes.

We notice also that in accordance with the decision of the Paris Conference on Fundamental Stars, held in May 1896, the constants of precession, nutation, aberration and solar parallax, as set forth at that meeting, have been adopted. The new value for the solar parallax is, therefore, 8"·80 instead of 8"·848, and this is probably correct to within 0"·02.

Part I. of the *Almanac* is issued separately, as of late years, and contains such information as is essential to navigators.

VARIABLE STAR U PEGASI.—In a recent issue of NATURE, p. 352, we noted Mr. O. C. Wendell's observations of the short-period variable, made at the Harvard College Observatory, and the results of which were issued by Prof. Pickering in Circular No. 23. In the *Astronomical Journal*, No. 426, Mr. Chandler brings data together to show that the light curve is, as was originally laid down, of single period, and not analogous to that of β Lyræ, with a small difference of 0·15 mag. between the primary and secondary minima. He also points out that the polarising photometer failed to make manifest the secondary minimum of the star Z Herculis, a phenomenon involving a difference of nearly 0·5 mag., or three times the amount in question.

In Circular No. 25 (on polarising photometers), Prof. Pickering points out that the objections to the first form of photometer have been remedied, and now the emergent pencils of the images compared coincide, and a surprising degree of accuracy may be obtained in the measures, which is illustrated by numbers from actual observations. He also gives the individual results derived from Mr. Wendell's observations, and these show that the largest value of the secondary minimum is 0·05 mag. less than the smallest value of the primary minimum. Besides this he shows that if the minima be assumed to be equal, the residuals at first minimum have a mean value of +0·064, and at the second the mean value is -0·070. He concludes that "the probability, therefore, that the two minima are really equal and that these deviations are due to accidental error is extremely small; and it is very singular that if these deviations are due to systematic error, that it has one value at principal minimum and another at secondary minimum."

THE PHOTOGRAPHY OF NEBULÆ.

PHOTOGRAPHY has been a helpful handmaid in many branches of astronomical science, but in no department is the value of her assistance more clearly seen than in that which is concerned with the forms and structures of nebulæ. This is hardly to be wondered at when the fine texture, the almost imperceptible gradations of light, the intricacy of detail, and the variety of nebulous forms are considered. Many vigils must be kept by an astronomer before the trend and comparative distinctness of a particular nebulous feature is satisfactorily observed; and even where this has been done, to represent the characteristic faithfully is beyond the power of any but the most accomplished draughtsmen. The unimaginative photographic plate, however, looks heavenwards for a few minutes and has imprinted upon it not only the delicate details which tease the eye of the observer and elude the skill of the artist, but also records a greater extent of celestial mist than the human eye is capable of grasping. On this account exceptional interest is attached to what has been accomplished in the portraiture of nebulæ, and the following survey of the subject will serve to show some of the roads along which progress has been made.

EARLY DAYS OF NEBULAR PHOTOGRAPHY.

Dr. Henry Draper was the pioneer of nebular photography; he succeeded in obtaining a photograph of the nebula of Orion on September 30, 1880. (“Washington Observations,” vol. xxv., 1878. Appendix i. p. 226.) Only the brightest parts of the nebula were comprised within the picture; nevertheless, the result was such as to show that photography had great possibilities before it as a delineator of nebulæ. Encouraged by the tangible fruits of his labour, Dr. Draper took a number of photographs of Orion's nebula, and in March 1881 obtained a picture showing stars fainter than the fourteenth magnitude; that is, stars only just within the limits of visibility of the telescope employed in the work. This fact was not lost upon him, for in a short note communicated to the Paris Academy of Sciences in April 1881 (*Comptes rendus*, vol. xcii. p. 964, 1881), he remarked that astronomers might reasonably expect to photograph stars which were quite beyond the visual reach of the most perspicuous observer; in other words, that a sensitive plate at the eye-end of a telescope could see objects which were too faint to produce any impression upon the retina of an observer using the same instrument. The picture which led to this remark was taken with an exposure of 104 minutes. Towards the beginning of the following year, a fine negative was produced by exposing a gelatino-bromide plate to the nebula for 137 minutes. This photograph comprised more of the nebulous matter, and especially of the delicate outlying parts, than any of the previous ones. In commenting at the time upon the strikingly perfect representation of the nebula afforded by the picture (“Washington Observations,” vol. xxv.; Appendix i. p. 227), Prof. E. S. Holden compared it with Bond's drawing of the same object. This observer spent several years scrutinising the nebula, and, as a result of his patient observation, was able to produce a picture which represented its features with greater accuracy and artistic effect than had previously been attained. Dr. Draper's photograph of the nebula was taken in a little over two hours, yet Prof. Holden confessed that for nearly every purpose it was incomparably better than Bond's hand-drawn picture. It was evident from this that a new epoch of nebular observation had been opened. Exact and automatic representations of nebulæ were to take the place of the strange, and often crude, drawings of these objects. The new method inaugurated by Dr. Draper has developed so much that, at the present time, it may almost be said that photography entirely holds the field as a nebula-artist.

A nebula rarely has a definite form, like the sun and moon. It presents the appearance of a cloud having more or less irregular outlines, and of which the various parts differ greatly in brightness. It results from this that photographs of the same nebula may be very different in appearance, for their characters depend upon the power of the telescope employed in their production, the time during which the sensitive plate was exposed, the sensitiveness of the plate, the transparency of the atmosphere, and many other causes. While Dr. Draper was working upon the Orion nebula in America, Dr. Janssen was experimenting at Meudon with a view of determining the influence of some of the variable conditions upon the results obtained (*Comptes rendus*, vol. xcii. p. 261, 1881). By taking photographs with exposures of five, ten, and fifteen minutes respectively, the eminent French investigator found that the longer the nebulous light was beating upon the sensitive film, the greater was the extent of nebulosity portrayed. It was this fact which permitted Dr. Draper to obtain his epoch-making picture, and has led to even more remarkable results during the past few years.

So long ago as 1874, Dr. A. A. Common was engaged in celestial photography, but it was not until May 1882 that he exhibited a photograph of the nebula in Orion (*Monthly Notices, R.A.S.*, vol. xliv. p. 222, 1883-84). The instrument used by him was a reflecting telescope three feet in diameter, specially constructed for photographic work. Such a large instrument is necessarily difficult to adjust and drive, and a laborious series of experiments had to be made before it could be said to be in working order. But the time spent in devising improvements was well repaid by the photograph of the Orion nebula taken by Dr. Common in January 1883. The photograph showed details of the nebula never before properly represented by the hand, and which can hardly be discerned by the eye. With the confidence that comes from experience, it was then predicted that “we are approaching a time when photography will give us the means of recording in its own inimitable way the shape of the nebula and the relative brightness of the different parts, in a better manner than the most careful hand-drawings.”

This prophecy was strikingly fulfilled in less than three years after it was made.

THE PLEIADES NEBULA.

In the early part of the year 1885 a fine photographic telescope was added to the equipment of the Paris Observatory, and placed under the control of two brothers, MM. Paul and Prosper Henry. The instrument had only been mounted a few months when it was used to photograph a cluster of stars—the Pleiades—which has attracted attention from time immemorial. The picture obtained showed truthfully the relative positions and grandeurs of the stars in and near the beautiful bunch of lucid points to which the telescope had been directed. But it was not so much the imprints of hundreds of stars that made the picture interesting to astronomers, as the fact that a new nebula appeared upon it. Round “stately Maia”—a star just visible to the naked eye—several wisps of nebulosity were clearly portrayed. Three further photographs of the same celestial region confirmed the existence of this nebulous matter, though no trace of haziness had previously been detected by ordinary telescopic observation (*Monthly Notices, R.A.S.*, vol. xlvi. p. 98, 1885-86).

It is a remarkable fact, however, that when an object has been discovered an observer is frequently able to see it, though he may have passed it over many times in previous surveys. So it was with the nebula round Maia. Very shortly after the announcement of the discovery had been made, M. Struve turned the 30-inch refractor at Pulkova towards the star to which attention had been directed, and found that he could distinctly see the nebulous surroundings (*Comptes rendus*, vol. cii. p. 281, 1886).

But faint objects are not only overlooked by the observer while viewing celestial scenery through his “optic tube”; they often go undetected on photographs themselves. The announcement of the discovery of the nebula recalled to Prof. E. C. Pickering's mind that certain irregularities had been noticed in a photograph of the Pleiades taken at Harvard College Observatory on November 3, 1885 (*Astronomische Nachrichten*, vol. cxiii. p. 399, 1886), that is, thirteen days before the MM. Henry obtained their first photograph showing Maia's nebulous surroundings. A re-examination of the Harvard College picture confirmed his surmise that the markings, which had previously been passed over as blemishes, were really the wisps of nebulosity photographed at Paris. Extending the scrutiny to the remainder of the Pleiades, indications of nebulous light were found about Merope, and a strange narrow streak was seen projecting from Electra. The Paris photographs showed similar appendages to these stars. This was not, however, a new discovery; the nebula near Merope was seen by W. Tempel while observing at Venice as far back as 1859 (*ibid.*, vol. liv. p. 286, 1861), and though several astronomers unsuccessfully searched for the object, many illustrious observers had attested to its existence (*Monthly Notices, R.A.S.*, xl. p. 622, 1879-80). Photography established the reality of Tempel's observations; and what is more, it was soon able to show that the faint patch, which had been the subject of so much discussion, was but a bright part of a vast nebulosity, in which the clustering stars were immersed.

Dr. Isaac Roberts was the astronomer who brought to light the wonderful extensions round the Pleiades. His work in celestial photography has been so fruitful in results, that a brief record of its growth will not be out of place. In 1883, Dr. Roberts made a series of experiments to test the suitability of ordinary photographic lenses for the delineation of celestial objects ("Photographs of Stars, Star-Clusters, and Nebulæ," I. Roberts, 1894). The results were so promising that he determined to develop the photographic method of observation, and, with this end in view, he ordered to be constructed a reflecting telescope of twenty inches diameter, and one hundred inches focal length. The instrument was ready for use in April 1885, and work was then commenced with it. But it was not until more than a year later that its performances began to reach Dr. Roberts's expectations. Only those who have had to coax astronomical instruments into a tractable condition, can understand and appreciate the difficulties with which he had to contend. It was found that satisfactory photographs could not be obtained until the driving-clock of the telescope had been greatly improved in regard to its ability to keep the instrument accurately following the apparent movements of the stars. When a sensitive plate has to be exposed to starlight for three or four hours, the beams from individual stars must continually beat upon the same spot, otherwise the stellar images do not appear as circular discs upon the resulting picture. To attain this desideratum—that is to say, to make a clock capable of driving a telescope so as to keep absolutely the same time as the stars—taxes the instrument-maker to his utmost; and, when Dr. Roberts commenced his work, there was no controlling clock that completely supplied the want. His early photographs, therefore, did not exhibit the stars as perfectly circular spots, nevertheless they greatly extended the state of knowledge of the Pleiades nebulosities. In October 1886, the first of his remarkable long-exposure photographs was obtained, the sensitive plate being kept directed to the Pleiades for three hours. With regard to the amount of nebulosity shown, the resulting picture was far in advance of all previous ones. It demonstrated that the MM. Henry had merely picked up the fringe of the nebulous matter round the Pleiades, for not only were all the stars of the cluster shown to be shrouded in nebulæ, but, to quote Dr. Roberts's words (*Monthly Notices, R.A.S.*, vol. xlvii. p. 24, 1886-7), "the nebulosity extends in streamers and fleecy masses, till it seems almost to fill the spaces between the stars, and to extend far beyond them. It suggests the probability that these stars in the Pleiades, together with many of the stars around them, are involved either directly or else in slight alignment with one vast nebula." This surmise was more than justified by future results. A year after it was made, the Henrys succeeded in obtaining a photograph which confirmed it. They, like Dr. Roberts, had been working towards perfecting their new engine of research. By the use of more sensitive plates, and by increasing the duration of exposure, they were able to bear witness that the feeble traces of nebulosity shown around the stars Maia, Merope, and Electra, on the views taken two years previously, appeared on the new photographs as bright nebulous masses, all more or less merging into one another, while an extensive lucid patch surrounded Alcyone (Observatoire de Paris, *Rapport Annuel*, 1887). Threads of nebulosity were also revealed, projecting from the central mass and having stars strung upon them like beads on a rosary.

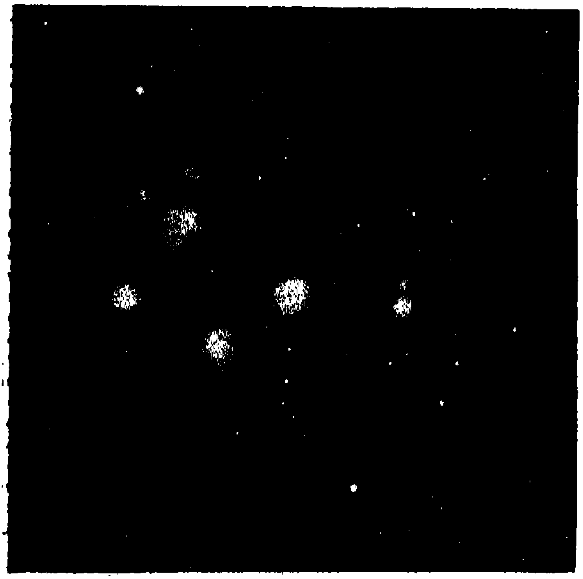

FIG. 1.—The Pleiades Nebula. (From a photograph by Dr. Roberts, with an exposure of ten hours.)

Until recently, the best result of Pleiades photography was reached by Dr. Roberts at the end of 1888 (*Monthly Notices, R.A.S.*, vol. xlix. p. 120, 1888-89). The view of the wonderful group then obtained was produced by exposing the sensitive plate for four hours. It showed more clearly and more beautifully the filmy sea in which the stars are immersed, but did not extend the limits defined by the earlier pictures. The *ne plus ultra* of Pleiades photography was lately obtained by Dr. Roberts with an exposure of ten hours, and a reproduction of the picture is here given (Fig. 1). No process of reproduction can, however, do justice to the brilliant picture which Dr. Roberts has permitted us to reproduce.

The epoch-making views of the Pleiades obtained ten years ago gave a great impetus to nebular photography. The thought that for a time to be reckoned in æons, the gauze-like veil on which the Pleiades were studded had been unable to affect man's visual perceptions, but could register its existence automatically upon a prepared surface, was sufficient to open up a vista of marvellous possibilities.

Dr. Roberts's photograph of the Pleiades nebula has become a classic. Of his numerous other photographs of nebulæ, three have attained a like eminence; they represent the Great Nebula in Orion (to which reference has previously been made), the Great Nebula in Andromeda, and the Spiral Nebula in the constellation of Canes Venatici, and to these attention must here be confined. It is perhaps invidious to select these pictures from the collection of five hundred photographs of nebulæ and clusters with which Dr. Roberts has enriched astronomy, for every one of his photographs adds to what was previously known about the objects portrayed. The nebulæ above designated, however, were all made to record their own forms at about the same time, and each of the monochromes produced exhibited striking novelties.

THE ORION NEBULA.

A photograph of the Orion nebula taken by Dr. Roberts in November 1887, though only representing a tentative result, showed nebulous matter covering an area quite seven times greater than that covered by Dr. Common's photograph (*Monthly Notices, R.A.S.*, vol. xlvii. p. 89).

What Dr. Roberts had gained in extent, however, he had lost in detail. The delicate structure of the central part of the nebula appeared but a splash of white upon the print presented to the Royal Astronomical Society, though it is fair to add that they could be distinguished upon the negative. The lesson learned was, that it was extremely difficult to obtain upon one and the same print a representation of the nebula showing it to the fullest extent, and also exhibiting the fine markings and imperceptible gradations that characterise such objects. An increase of the time of exposure certainly increases the area of nebulosity depicted upon a photographic plate; but while the picture is having its limits extended, the filmy rays in the brighter regions of nebulosity are being "burnt out" by the cumulative action. This difficulty has now been overcome; for since Dr. Roberts revealed to astronomers the vast extent of the Orion nebula, he has taken, upon a single plate, photographs which show the fine detail of the nebulous structure as well as the great sky-area covered by the nebulous mass. One of these pictures, taken with a dual exposure of seven hours thirty-five minutes, on two evenings in February 1894, is here reproduced (Fig. 2), and it represents, according to Dr. Roberts, "the maximum of extent and detail that can be shown by aid of photographic methods." The illustration is, however, but a feeble representation of the original picture. Longer exposure with a reflecting telescope, such as that used by Dr. Roberts, would result in the photographic plate being fogged by the general luminosity of the sky sufficiently to obscure dim nebulous streamers and faint stars. With a refracting telescope Dr. Gill has given an exposure of nearly twenty-five hours to the nebulous region around Eta Argus, without the film of the photographic plate being much darkened, but the conditions with a refractor are not precisely similar to those which obtain in the case of a reflector having a short ratio of focal length to aperture.

It appears, however, from some photographs recently taken by Mr. W. E. Wilson, F.R.S., and exhibited at the Royal Astronomical Society, that the time of exposure needed by the photographic plate to depict the greater part of the Orion nebula may be considerably reduced. Mr. Wilson uses a reflecting telescope of twenty-four inches aperture, and ten feet six inches focal length, constructed by Sir Howard Grubb, and provided with his usual type of driving-clock and electrical control. With this instrument, and an exposure of only forty minutes, he has been able to produce a portrait of Orion's great nebula which, as regards structural detail, will bear comparison with any previously obtained. Good photographs of the Orion nebula and other nebulæ have also lately been taken at the Paris Observatory with exposures of an hour or less (see p 374). A comparison of Mr. Wilson's photograph of the Orion nebula with one recently taken by Dr. Roberts with the same exposure shows that they both contain about the same amount of detail and extent of nebulosity, so the decrease of the time of exposure is probably to be accounted for by the use of more sensitive plates than were formerly available. The central part of the Orion nebula, as photographed in forty minutes, is here reproduced by the side of a well-known drawing of the nebula lithographed by Mr. L. Trouvelot in 1864, from drawings made by Prof. G. P. Bond, of the Harvard College Observatory (Fig. 3). We have thus what is undoubtedly the best drawing of the nebula compared with a good photograph on the same scale (Fig. 4), and though much of the fine detail in the latter picture has been lost in reproduction, the difference between the work of the hand and that of the photographic plate is very striking.

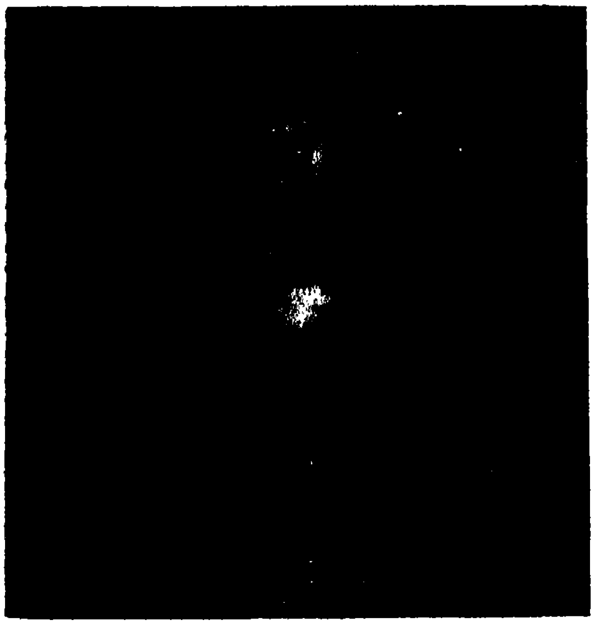

FIG 2.—Great Nebula in Orion. (From a photograph obtained by Dr. Roberts, with an exposure of 7½ hours.)

Prof. Bond had to use every available hour for about five years in order to determine accurately the structure and distribution of the parts of the nebula. Such devoted perseverance cannot but command admiration, yet, except for the satisfaction which the celestial draughtsman derives from his work, a like expenditure of time and energy would now be almost useless. It is not, however, for the celestial photographer to depreciate the labours of the plodding observer. As Dr. Roberts himself has said, "we ought, with all gratitude, to admire the patient, long-suffering endurance of those martyrs to science, who, during the freezing nights of many successive winters plotted, with pencil in benumbed fingers, the crude outlines which have been handed down to us as correct drawings of this wonderful nebula, which we can now depict during four hours of clear sky with far greater accuracy than is possible by the best hand-work in a life-time" (*Monthly Notices, R.A.S.*, vol. xlix. p. 297, 1888-89).

THE SPIRAL NEBULA IN CANES VENATICI.

The years 1888-89 will be marked with a white stone in the annals of celestial photography, for it was then that so many remarkable proofs of its great capabilities were presented to the astronomical world. A photograph of the wonderful spiral nebula in the constellation Canes Venatici was obtained by Herr von Gothard in 1888 (*Astronomische Nachrichten*, No. 2854, 1888), and by Dr. Roberts in April, 1889 (*Monthly Notices, R.A.S.*, vol. xlix. p. 389, 1888-89). Dr. Common appears to have taken a good photograph of the nebula in 1883, but he did not publish any description of it at the time (*Observatory*, vol. xi. p. 393, 1888). An accurate picture of the object was certainly much needed. The nebula had been drawn by Herschel, Rosse, Lassell, and numerous other astronomers, and its convolutions had been more or less symmetrically traced. But so long as only drawings, differing widely from one another, existed of the spiral nebula in Canes Venatici, little was learned about the physical nature of the object. The photographs showed that the whorls of nebulosity were knotted with bright spots—stars in the course of formation—and these followed so closely the trend of the streams of nebulous matter, that their connection with it was placed beyond the possibility of doubt. The picture is a striking view of a stage of progress in the evolution of stellar systems; it exhibits in a most unmistakable manner a "fluid haze of light" eddying into worlds, and enables us almost to see cosmic processes at work. In the accompanying illustration the nebula, as observed with Lord Rosse's six-foot telescope and drawn by hand, is represented (Fig. 5) side by side, and on the same scale, as a photograph of the object obtained by Mr. Wilson with an exposure of forty

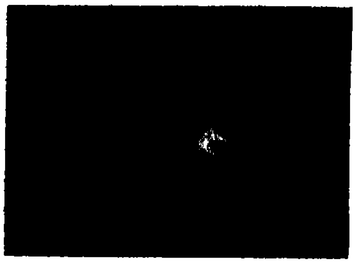

FIG. 3.—Bond's drawing of the Great Nebula in Orion (1859-63).

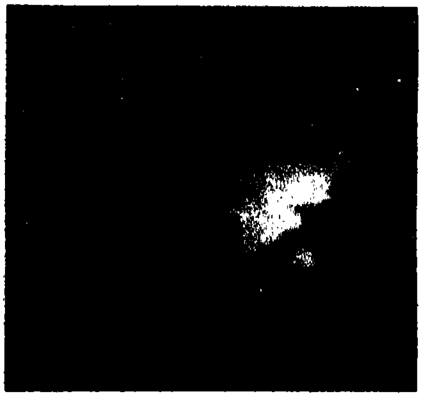

FIG. 4.—Photograph of the Great Nebula in Orion, obtained with an exposure of forty minutes.

minutes (Fig. 6) Considered as pictures, the drawing is perhaps more attractive than the photograph, but this is because the photograph has been enlarged to such an extent that the grain of the film is shown. The comparison should be made between the original negative and the drawing, in order to be able to appreciate fully the assistance given by photography to the delineation of the structure of the nebula.

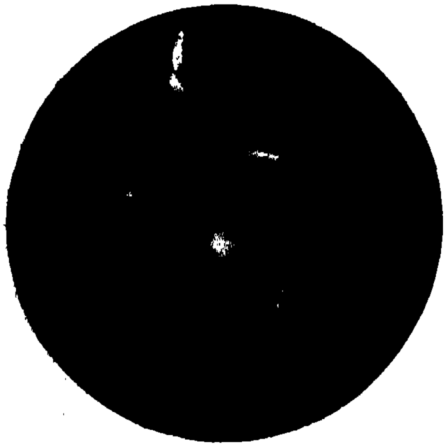

Fig. 5.—From a drawing.

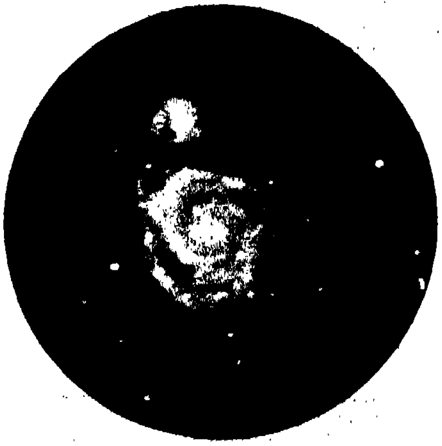

Fig. 6.—From an enlarged photograph by Mr. W. E. Wilson.

The Spiral Nebula in Canes Venatici.

The Andromeda Nebula.

Until Dr. Roberts took the photograph of the nebula of Andromeda in 1888 (*Monthly Notices R.A.S.*, vol. xlix. p. 65, 1888–89), astronomers did not understand that this object was a remarkable example of the ring-stage in celestial evolution.

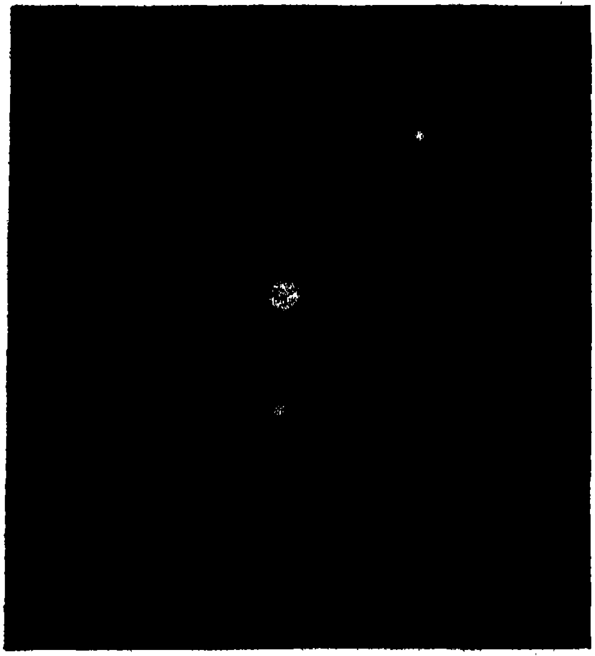

Fig. 7.—The Andromeda Nebula. (From a drawing by Bond and Trouvelot.)

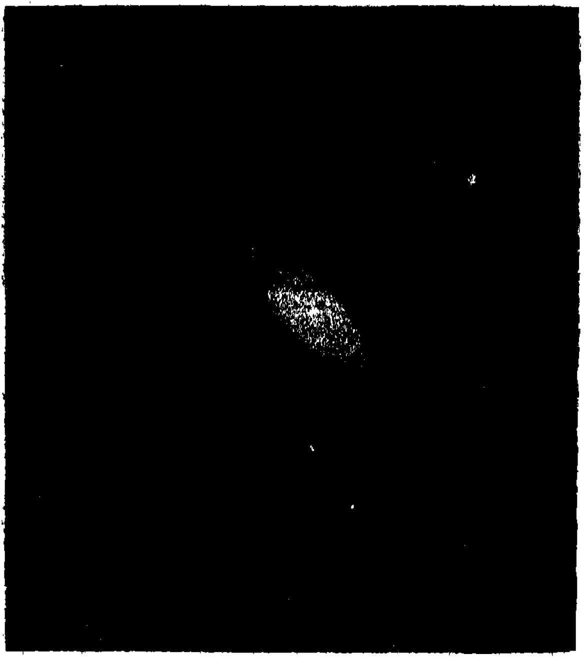

Fig. 8.—The Andromeda Nebula. (From a photograph obtained by Dr. Roberts, with an exposure of ninety minutes.)

Bond's drawing (Fig. 7) was acknowledged to be the finest representation of the nebula, but how much it is inferior to the photograph (Fig. 8) is shown in the accompanying comparison of the two. It will be seen that the major axis of the small nebula near the top on the right has a different relative position in the two pictures, when considered with reference to the great nebula. The difference may indicate a change in the direction of the axis between 1847, when the drawing was made, and now, but it would be unwise to conclude that this difference is real, seeing that the distinct statement is made that "the lithograph represents somewhat inaccurately the relative positions of the chief nebulous centres of condensation" (*Annals of Harvard College Observatory*, 1876). But though this possible change is important in itself, it is not so instructive as the rings of nebulosity seen surrounding the bright central portion of the great nebula on the photograph. The dark lanes drawn by Bond are seen upon the photograph to be divisions between the zones of nebulous matter; and what visually appears to be accidental and enigmatical vacuities, are shown photographically to be the consequences of cosmogonical action. The hypothesis of the formation of worlds from nebulæ was thus confirmed, if not demonstrated, by the discovery of this new link to connect celestial species.

THE PORTRAIT LENS IN NEBULAR PHOTOGRAPHY.

It was at one time supposed that large telescopes were necessary to obtain valuable pictures of celestial objects; but as the work went on, it was found that ungainly instruments were not at all essential, and that excellent results were given by instruments of very moderate dimensions. For photographing faint stars, where the images on the photographic plates are practically points, the aperture of the object-glass or mirror is almost the only factor to be taken into account in estimating efficiency; but for nebulæ, comets and similar celestial objects, the images of which cover sensible areas on the plates, the ratio of focal length to aperture is all-important, and the actual aperture is a secondary consideration.

Experience has shown that a lens constructed in the same way as a portrait lens for use in an ordinary camera, is really the best instrument for several branches of celestial photography. The lens must of course be mounted, so that it can be made to follow the motions of the celestial sphere, but in other respects the camera need not differ essentially from that used in the ordinary portrait studio. The advantage of the portrait lens over the photographic telescope is that the field of view is much greater—it is therefore able to take a broader view of things.

The telescopes used for the international star catalogue and chart may be taken as the standard instruments for *star* work. The aperture of the object glass is 13 inches, and the focal length, roughly, 130 inches (ratio 1 to 10), the effective field being a little over 2 degrees square (4 square degrees on the celestial sphere). A portrait lens of 6 inches aperture and 30 inches focus (the favourite size with those who use portrait lenses for celestial photography) has a ratio of aperture to focal length of 1 to 5, and an effective field of 15 degrees square (225 square degrees). In photographing a nebula, this portrait lens only requires about one-half the exposure necessary when the standard telescope is used, while the area covered is nearly forty times as great. It follows, therefore, that for an extended nebula covering over 100 square degrees on the celestial sphere—and such nebulæ exist, and have been photographed—the portrait lens can give in two hours a complete picture comparable, in area of sky covered, with a picture that would require twenty-five exposures of four hours each with the standard star telescope; and that, whereas the picture with the portrait lens would all be on one plate and taken with one exposure, that with the standard telescope would be a mosaic built up from at at least twenty-five plates taken at different times, and consequently under very various atmospheric and astronomical conditions.

During the past eight years or so, a large number of photographs of nebulæ and nebulosity have been obtained by means of portrait lenses; and year by year the work done, both in this and other branches of astronomical photography, has been admirably summarised by Mr. Albert Taylor in the *Photography Annual*. Every one interested in the progress of celestial portraiture should refer to these annual records of results, as we have had frequently to do in preparing the subjoined account of the use of the portrait lens in astronomical photography.

The great advantage of the portrait lens or doublet over the telescope was admirably brought out by Prof. W. H. Pickering, who, using a small camera at Wilson's Peak, California, in 1889, obtained a photograph including on one plate the whole constellation of Orion. The great nebula in Orion was clearly shown, but the chief value of the photograph lies in the large number of detached nebulous patches shown, which appear to be part of an enormous zone of nebulosity encircling the great nebula, and practically covering the entire constellation. The existence of this great mass of nebulous matter, and its obvious connection with the well-known nebula in the sword-handle of Orion, would probably never even have been discovered with long-focus instruments with small photographic fields; yet with the portrait lens it is a comparatively easy object.

In 1890, Mr. H. C. Russell, F.R.S., obtained a large number of striking photographs of nebulæ and the Milky Way with a 6-inch Dallmeyer portrait lens attached to the mounting of his telescope. The pictures thus obtained show many details of structure which are quite invisible in the telescope. Exposures of between four and five hours brought to light many peculiarities of arrangement of stars in Nebecula Major and Minor—the Magellanic clouds—and showed that the whole of the former apparently detached portion of the Milky Way had the structure of a complex spiral nebula with two nuclei two degrees apart. The Nebecula Minor as portrayed by Mr. Russell's camera bears a resemblance to the well-known Dumb-bell nebula.

Following closely on Prof. W. H. Pickering's work in 1889, the greatest advances in the photography of nebulæ in 1891 were due to Prof. Barnard at the Lick Observatory, Dr. Max Wolf at Heidelberg, Mr. Russell at Sydney, and Dr. Archenhold at Helensec, each of these observers using ordinary portrait lenses.

Dr. Max Wolf, with a 2⅓-inch aplanatic lens of 7⅜ inches focus, photographed in one hour all the nebulæ in the Pleiades obtained by the Brothers Henry at Paris with four hours' exposure with the 13-inch charting telescope; and afterwards using a 4-inch Vöigtlander Euryscopic lens and a 5-inch Kranz Euroscopic lens, Wolf obtained more extension of the great nebula in Orion in 4 hours than Dr. Roberts had obtained with 4½ hours' exposure with his 20-inch mirror. These same plates of Wolf amply confirmed Prof. W. H. Pickering's results, and revealed an enormous amount of new detail in the nebula around ζ Orionis.

Turning his attention to the constellation Cygnus on June 1, 1891, Dr. Wolf, by 3 hours' exposure with the 5-inch Kranz lens, discovered an enormous nebula full of the most complex structure, and connecting a number of bright stars with many fainter ones in the Milky Way (*Astr. Nach.*, 3048). Starting apparently from a central point, the nebula spreads out branches which curve and meet "fold on fold of nebulous matter surging over the sky" and "becoming notably compact and luminous in the immediate neighbourhood of γ Cygni." Some of these branches are 8° long, so that at least four plates would be required for one of them with a photographic telescope of standard size; but the portrait lens secures all on one plate, and their true relations to each other and to the involved stars become at once apparent.

The great feature of this photograph, and of many subsequent pictures, is the obvious connection between bright stars and fainter ones. It was formerly believed that the brightness of a star was to some extent a measure of its distance from us, but the photographs with portrait lenses effectively disposed of this idea. Stars of nearly first magnitude were found to be joined to stars of the eighteenth magnitude by wisps of nebula, and to obviously form part of the same system in the heavens. These stars, the brightest of which are about 4,000,000 times more luminous than the faintest, must be at practically the same distance from us, and their differences in brightness must be due to differences of size or physical condition, or both, and not to any differences in distance.

Another interesting result from the photographs was the proof of the connection of nebulæ with stars of the Wolf-Rayet type of spectrum—stars with bright lines in their spectra—which Sir Norman Lockyer classifies as stars only just condensed from nebulæ, and next in order of evolution. Dr. Roberts, with 3½ hours' exposure with the 20-inch mirror, could detect no nebulosity round these stars in Cygnus, but the portrait lenses with exposures extending up to 13½ hours, indicated that all these stars are nebulous.

This work of Wolf was supplemented by some splendid results obtained by Mr. Russell at Sydney Observatory about the same time. The lens used, a 6-inch Dallmeyer of 30 inches focus, gave, with three hours, as much extension of the great nebula round the star η Argus as the 13-inch charting telescope showed with twice that exposure, while the relations of the nebula to the surrounding stars were much better shown. Two long exposures with the same lens on those curious detached portions of the Milky Way in the southern heavens, known as the Nebeculæ Major and Minor, revealed a great amount of previously unknown nebulous matter, much of which would be very difficult to obtain with larger instruments.

Dr. Archenhold, at Helensec, recognising the true principles of photography of celestial objects of large size, had two lenses constructed by Busch, the ratio of aperture to focal length being 1 to 4·5 and 1 to 2·5 respectively. With these lenses he photographed a very striking and extensive nebula near ξ Persei on October 27, 1891, with 32½ minutes' exposure. This new nebula resembles in many respects the great nebula in Andromeda, but probably covers a much greater area of the sky. The great effectiveness of this special lens is shown by eye observations with a 12-inch telescope; for even with the photograph to indicate where to look for details, scarcely any trace of the nebula can be made out (*Astr. Nach.*, 3082). Dr. Scheiner, at Potsdam (*Astr. Nach.*, 3157), has photographed this great nebula with a 4-inch portrait lens, giving exposures up to six hours. The spiral form is clearly shown, while the extent of the nebula is greatly increased.

Prof. E. E. Barnard, with the 6-inch Willard lens of 30 inches focus at the Lick Observatory, has enormously extended our knowledge of these great diffuse nebulosities. It is quite impossible in the limits of this article to deal with these in detail, but the extraordinary form of the nebula round 15 Monocerotis, the enormous diffuse nebulosities in the constellation Cepheus and round the Pleiades, the tremendous extensions of the Orion nebulæ shown in his numerous articles in *Astronomy and Astrophysics* and the *Astrophysical Journal* since 1893, are all magnificent examples of the use of the portrait lens in photographing nebulæ; and one can have no hesitation in saying that without the portrait lens we should still be in ignorance of many of these wonderful objects. But Barnard has gone beyond the portrait lens, and has used the lens of a cheap oil lantern, the effective aperture of which is about 1½ inches, the focal length being 3½ inches, ratio 1 to 2·3. This gives a field of 30 degrees practically flat, the scale of the photographs being 10·3 degrees to 1 inch on the plate. Twenty photographs in October 1894 (*Astronomy and Astrophysics*, vol. xiii. p. 811) fully brought out the value of this instrument. One hour's exposure gave all the Andromeda nebula; thirty minutes gave all the diffuse nebulosity round the Pleiades photographed by Archenhold in four hours, and by Barnard with the Willard lens in three hours. The most valuable of all results, however, were those with Orion, obtained on October 3 and 28, 1894, with exposures of 2h. and 1h. 15m. The extensive spiral detected by Pickering in 1889 is fully shown in correct proportion, and "no description can give any idea of the form and magnitude of this nebula." Extending over 17 degrees in length and nearly the same in breadth it includes almost all the stars of the constellation, and forms in fact a robe for the body of the giant. The well-known "great nebula of Orion" is but a pigmy compared with the greater nebula revealed by Prof. Barnard's plates, and it is not too much to believe that longer exposure will probably fill the whole constellation with nebulosity, and show that the great nebula is simply the inner termination and the brightest part of the enormous spiral.

An English amateur, Dr. E. M. Sheldon (*Journal of the British Astronomical Association*, vol. v. p. 397), using a lantern lens similar to that used by Prof. Barnard, photographed this enormous spiral in Orion with 1¼ hours' exposure, in February 1895. Four hours on the constellation Cygnus with this lens gave all *the nebulæ on Wolf's photograph taken with 13 hours'* exposure.

The nebulosities in the Pleiades have attracted great attention since they were first photographed by the Brothers Henry at Paris in 1885. These nebulæ have always been remarkable *from their intimate relations with individual stars in the cluster*—"Maia is a diamond clasp on a curving plume, Electra extends a tentacle towards Alcyone, while Merope has a sweeping gauze trail and probably a nebulous satellite." In striking contrast to this we usually have in other regions of the sky stars and nebulæ *intimately mixed, although frequently* on *recent* photographs wisps of nebulæ are found joining stars, so that the structures appear to resemble festoons of pearls on a gauzy string. The most recent photographs of the Pleiades by Barnard at the Lick Observatory, taken 10h. 15m. exposure with the Willard (6-inch) lens; by Mr. H. C. Wilson, with a similar lens and 11 hours' exposure; and by Dr. Max Wolf, have revealed an enormous extension of the Pleiades nebulosity. The whole area is now 158 square degrees, and there are indications that even this is not the real limit, and that more prolonged exposures will give still greater extension, probably joining up the whole of the nebulosity into an enormous spiral similar to that covering the constellation Orion

Other photographs exhibiting the same class of structure have been obtained of the region round Antares with 7½ hours' exposure by Prof. Barnard at the Lick Observatory. At first sight this new nebulous mass would easily be mistaken for the Pleiades Nebula, and it is a remarkable and very significant fact that both these masses and all other great nebulosities in the Milky Way either occupy vacancies amongst the stars, or are on the edges of such vacancies; and that in their immediate neighbourhood the stars exhibit long vacant lanes and other remarkable features, indicating that the nebula, stars, and vacant lanes are but different features of some vast and at present imperfectly comprehended system of celestial grouping.

The first results obtained by Prof. Bailey, at Arequipa, with the Bruce photographic telescope of the Harvard College Observatory have lately been recorded. This portrait lens, the largest in the world at present, has an aperture of 24 inches and a focal length of 135 inches, so that while the scale of the photographs is equal to that of the international star charts (1 minute of arc to 1 millimetre), the light-gathering power of the telescope is three times as great, and exposures with this instrument need be only about one-third of those required with the standard international telescopes to achieve the same results. But the Bruce telescope has a further advantage over the standard instruments. Its effective field is 25 square degrees (14-inch by 7-inch plates are used), whereas the effective field of the international instruments is only 4 square degrees in area. The daring experiment of Prof. Pickering in devising, and Mr. Alvan Clark in constructing, this enormous portrait lens has been completely successful (although several eminent astronomers on this side of the Atlantic doubted whether such an instrument could be constructed), and as a result we have an instrument which can do all the international work on less than 4000 plates and with very much reduced exposure. Prof. Pickering does not at present intend to duplicate the work of constructing the photographic chart of the stars, but will confine the instrument to nebulæ and special regions of the sky, and, with the aid of a 24-inch object prism, to spectrum photography. The published preliminary results are of very great value.

This article ought not to be concluded without mention of the fact that more than one astronomical photographer is of the opinion that some of the nebulosity shown upon pictures obtained with small portrait lenses is not real, but due to diffused starlight. A warm controversy has *taken* place with *reference* to this point, but this is not the place to present the views of the two parties. It has been shown in this article that large instruments, such as those used for the International Chart, with long focal length but restricted fields, can give us pictures *full of delicate details of bright nebulæ*, and these photographs are of extreme value; but we must look to the portrait lens for the larger details and for the fainter nebulosities which are absolutely beyond the reach of any photographic object-glass or mirror. There can be no rivalry between the *two classes of instruments; each is perfect in its way, each will* mislead if solely relied upon. Photographs of the same nebulæ, both with long focus object-glasses or mirrors and with portrait lenses, are necessary, and must be used to supplement each other, if we are to get correct ideas of the phenomena of stellar *distribution and the connections between nebulæ and stars. The* "best instrument to use" is not a matter of personal experience nor of individual opinion: the optical and photographic laws bearing on the subject are well known, and the practical limits of atmospheric definition and instrumental construction are within sight. The ideal instrument for photographing nebulæ will probably combine large aperture, short focal length, and the large flat field of the portrait lens; will be, in fact, a glorified portrait lens: there are optical reasons why neither the object-glass nor the mirror can be wholly satisfactory. While waiting for this instrument, every possessor of an ordinary rectilinear lens with an ordinary camera can, by strapping his camera on to an equatorially mounted telescope and using infinite patience, materially advance our knowledge of nebulæ by means of photography.

R. A. GREGORY.

PHOTO-MICROGRAPHY WITH HIGH POWERS.

PHOTO-MICROGRAPHY has for some years past advanced but slowly, although its present status as a means of delineating minute structure is undoubtedly much higher than it has ever been. In optical appliances the improvements have been many, the most notable being the introduction of apochromatic objectives. Their greater aperture and freedom from effects of the secondary spectrum have combined to render it possible to obtain good results with much greater ease than formerly. Some of the photomicrographs obtained, however, in the early days of microscopy are even now hardly excelled, although they were produced at the cost of enormous labour, and required extraordinary skill on the part of the operator, with the apparatus then available. The production of satisfactory photographs, when the magnification exceeds one thousand diameters, has always been a matter of some difficulty. One of the greatest of these has been the want of a source of illumination which should be of sufficient intensity without a considerable increase in the size of the illuminating surface. Various attempts have been made to adapt the oxy-hydrogen light for the purpose; but there always remains the objection, that however small the incandescent portion of the lime may be, it does not emit light of equal intensity over the whole of its surface. This can at once be seen if an image of the lime be projected on to a screen. The result is uneven illumination, a defect so often seen in high-power photographs, when the image of the radiant is projected by the achromatic condenser across the object, or what is known as "critical illumination."

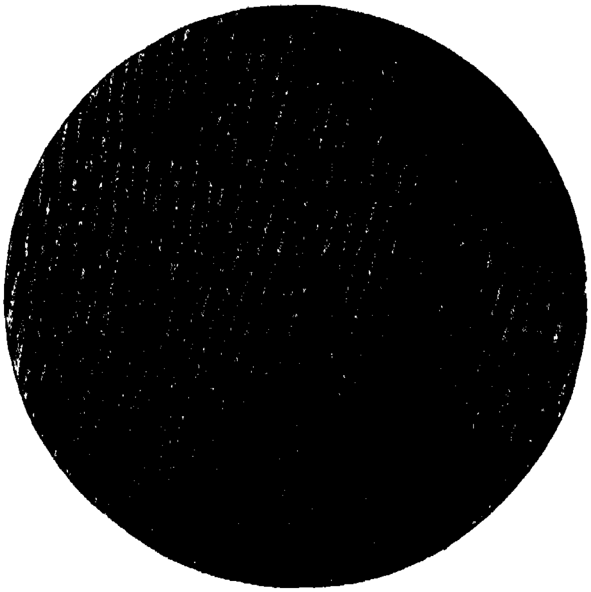

FIG. 1.—Surface markings on Podura scale. Photographed with Swift's 1/12-inch apochromatic, projection ocular 2, and central cone. Magnification, 2500 diameters.

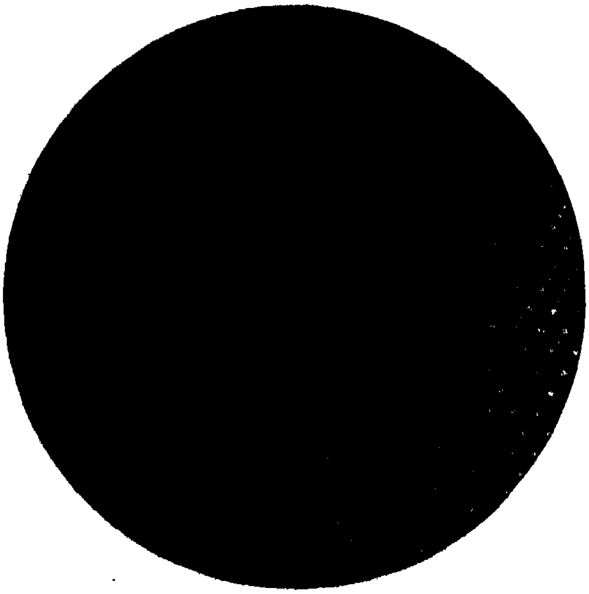

FIG. 2.—*Pleurosigma angulatum.* Photographed with Winkel's 1/20-inch homogeneous immersion, projection ocular 4. Central cone and malachite-green screen. Magnification, 5000 diameters.

The electric arc is the light which approaches most nearly to an ideal illuminant. The source of light is extremely small, but the intensity is great, and the incandescent surface is, if working under proper conditions, homogeneous. It has until recently been impossible to so control the arc that these conditions could be obtained with certainty. In all forms of lamp, whether hand-fed or automatic, the difficulty has been to maintain a constant position and condition of the crater on the positive carbon. This can be done by having a simple form of hand-feed apparatus with a pin-hole camera attached, through which an image of the carbon points is projected on to a ground-glass screen. Reference lines are provided on this screen, so that the length of arc and position of the positive crater can be continuously observed. The arrangement was exhibited at the two conversazioni of the Royal Society last year, and has been fully described before the Royal Microscopical Society. With such a form of arc-lamp absolute centiation of the light can be secured and maintained without reference to the microscope, after the necessary position of the image of the arc on the screen of the pin-hole camera has been once obtained. The accompanying illustrations have been reproduced from photographs taken with the arc-light so arranged. Fig. 1 shows the surface markings on a Podura scale, magnified 2500 diameters. Fig. 2 is a frustule of *Pleurosigma angulatum*, magnified 5000 diameters. In neither photograph is there the slightest sign of de-centration, and in both cases centration was maintained entirely without reference to the microscopic image.

THOMAS A. B. CARVER.

A METHOD OF MEASURING WIND PRESSURE.[1]

THERE are few physical problems of greater immediate and obvious practical importance, than that involved in the measurement of air pressures under complex conditions of motion, and there are few problems which present greater difficulty, or—what is worse—uncertainty. It may be comparatively easy to obtain under any particular set of circumstances evidences of barometric variation by means of some indicating instrument, apparently suitable for the particular purpose, but it is a very different matter to decide how far the quantitative result is unaffected by actions set up by the instrument itself. Thus the record of the pressure plate gives information which is of little, if any, value in relation to the distribution of pressure over a large building; while the barometer itself is capable of giving misleading indications, whether it is too effectually protected from external influences, or too much exposed.

For measuring the wind pressure at any point of a structure of considerable size, a receiver or collector is required, with a convenient gauge connected by a tube. It is essential that the collector should not itself give rise to compressions or rarefactions affecting the gauge. To the invention of such an instrument Prof. F. E. Nipher has devoted much attention, and his final apparatus seems to fulfil its purpose admirably. Two equal thin metal discs, 2·5 inches in diameter, having bevelled rims, are screwed together, so as to leave a small space between, into which a connecting tube is passed through the centre of one of the discs. The end of the tube is flush with the inner surface, and the interspace is filled up with a certain number of layers of fine wire screen, which project at least half an inch beyond the edges of the metal discs. When this simple device is placed in a stream of air, it is found that the effects of rarefaction and compression, set up at different parts of the porous screen, completely neutralise each other, so that the pressure at the mouth of the tube is the same as the true intrinsic pressure of the external air. This property of the collector was severely tested by thrusting it out of a carriage window in a train which was travelling at the rate of sixty miles an hour: no effect on the gauge could be noticed, although the instrument was sufficiently sensitive to show instantly the effect of placing the hand at a tangent to the edge. The gauge which Prof. Nipher employed was a water manometer consisting of a cylindrical vessel partly filled with water, with a straight glass tube leading out from the bottom and inclined at 5 in 100 to the horizontal. The open end of this tube was in communication with a collector of the form suggested by Abbe[2] so as to secure a standard pressure of comparison.

---

[1] "A Method of Measuring the Pressure at any Point of a Structure, due to Wind blowing against that Structure." By Francis E. Nipher. (*Transactions* of the Academy of Science of St. Louis, vol. viii. No. 1.)

[2] Report of the Chief Signal Officer, 1887, 2, 144.

Being now satisfied with the trustworthy nature of his apparatus, Prof. Nipher determined to apply it to the determination of the distribution of pressure over a large pressure board. For this purpose the board, which was a wooden one, 4 feet long by 3 feet wide, was mounted on the roof of a railway carriage. It was bolted to a vertical iron pipe, and the couple required to keep it perpendicular to the direction of the wind was measured by a spring balance. On opposite sides of the board, and at the centre of one of the 108 4-inch squares into which the board was divided, two disc collectors were fixed and connected by rubber tubes with their respective gauges. The latter, together with a third, which was used as a level, were mounted on a board which was rigidly attached to a heavy pendulum within the carriage. The speed of the train varied generally between twenty and fifty miles an hour, and was checked by direct observations.

The total action on the board is the result of an increase of pressure in front and a decrease behind. Both the increase and the decrease are shown by this series of experiments to be proportional to the force necessary to hold the board to the wind as indicated by the spring balance. Further, the force measured in this way differs from that deduced from the data given by the collectors by no more than 1 per cent., and although this may be in a measure accidental, it affords a confirmation of the accuracy of Prof. Nipher's method. On both sides of the board the difference from the ordinary pressure becomes less as the periphery is approached, although there is some evidence of a minimum excess at the centre of the front face. Prof. Nipher gives a few notes on the application of the device to the study of pressure variation around a building. It is to be hoped that such developments as this will be realised. At present it is too early to estimate the full importance of these researches as a contribution to the study of anemometry; but the idea is full of promise, and the simplicity of the apparatus is certainly a great point in its favour.

AN ENCHANTED MESA.[1]

THE pueblo of Acoma, in Western Central New Mexico, is the oldest settlement within the limits of the United States. Many of the walls that still stand on that beetling peñol were seen by Coronado during his marvellous journey in 1540, and even then they were centuries old.

The valley of Acoma has been described as "the Garden of the Gods multiplied by ten, and with ten equal but other wonders thrown in; plus a human interest, an archæological value, an atmosphere of romance and mystery"; and the comparison has not been overdrawn. Stretching away for miles lies a beautiful level plain clothed in grama and bound on every side by mesas of variegated sandstone rising precipitously from 300 to 400 feet, and relieved by minarets and pinnacles and domes and many other features of nature's architecture.

None of these great rock-tables is so precipitous, so awe-inspiring, and seemingly so out of place as the majestic isolated Katzimo or Enchanted Mesa, which rises 430 feet from the middle of the plain as if too proud to keep company with its fellows; and this was one of the many wonderful homesites of the Acomas during their wanderings from the mystic Shípäpu in the far north to their present lofty dwelling-place.

Native tradition, *as distinguished from myth, when uninfluenced* by Caucasian contact, may usually be relied on even to the extent of disproving or verifying that which purports to be historical testimony. The Acoma Indians have handed down from shaman to novitiate, from father to son, in true prescriptorial fashion for many generations, the story that Katzimo was once the home of their ancestors, but during a great convulsion of nature, at a time when most of the inhabitants were at work in their fields below, an immense rocky mass became freed from the friable wall of the cliff, destroying the only trail to the summit and leaving a few old women to perish on the inaccessible height. What more, then, could be necessary to enwrap the place for ever after in the mystery of enchantment?

This tradition was recorded in its native purity some twelve years ago by Mr. Charles F. Lummis, and the same story was repeated by Acoma lips to the present writer while conducting a reconnaissance of the pueblos in the autumn of 1895. During this visit, desiring to test the verity of the tradition, a trip was made to the base of Katzimo, where a careful examination of the talus (especially where it is piled high about the foot of the *great south-western cleft (Fig. 1) up which the ancient pathway* was reputed to have wound its course) was rewarded by the discovery of numerous fragments of pottery of very ancient type, some of which were decorated in a vitreous glaze, an art now lost to Pueblo potters. The talus at this point rises to a height of 224 feet above the plain, and therefore slightly more than half-way up the mesa side. It is composed largely of earth, which could have been deposited there in no other way whatsoever than by washing from the summit during periods of storm through many centuries. An examination of the trail to a point within 60 feet of the top exhibited traces of what were evidently the hand and foot holes that had once aided in the ascent of the ancient trail, (Fig. 2) as at Acoma to-day. Even then the indications of the former occupancy of the Enchanted Mesa were regarded as sufficient, and that another one of many native traditions had been verified by archæologic proof.

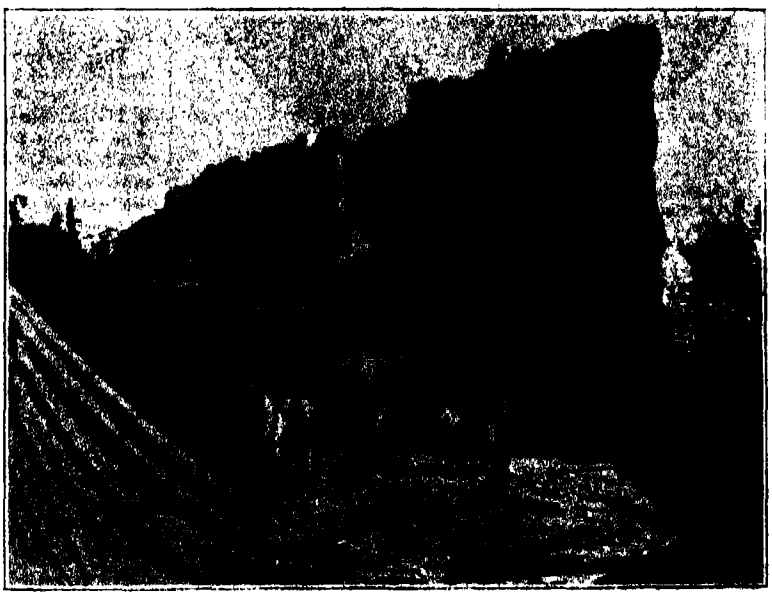

FIG. 1.—The Enchanted Mesa—the Great South-western Cleft and Talus Heap.

More recently the author visited Katzimo a second time, on this occasion with Major George H. Pradt, Mr. A. C. Vroman, and Mr. H. C. Hayt, in order to determine what additional data of an archæological nature might be gathered by an examination of the summit.

The ascent of the talus, in which the potsherds had been observed in such considerable quantities two years previously, was made in a few minutes, the ladders, ropes, and photographic and surveying instruments being carried with some effort, since *climbing, heavily laden, at an altitude of 6000 feet, in a broiling* sun, is no trifling labour; but the real work began when the beginning of the rocky slope of the cleft was reached. One member of the party, taking the lead, dragged the end of a rope to a convenient landing place, where a dwarf piñon finds sufficient nourishment from the storm-water and sand from above to eke out a precarious existence. Fastening the rope to the tree, the outfit was hauled up, and the other members of the party found a ready means of ascent. The next landing was several feet above, at the base of a rather steep pitch of about twelve feet. This wall, although somewhat difficult to scale, may be climbed with greater or less safety by the aid of several small holes in its face. These holes were doubtless made artificially, but as the narrow pathway at this point is now a drainage course during periods of storm, the soft sandstone has become so much eroded that they have apparently lost their former shape.

---

[1] Abridged from a paper by Mr. F. W. Hodge, of the United States Bureau of American Ethnology, in the *National Geographic Magazine*.

The summit of Encantada was reached after some difficulty. It has been swept and carved and swept again by the winds and rains of centuries since the ancestors of the simple Acomas climbed the ladder-trail of which we found the traces. The pinnacled floor has not always appeared as it is to-day, for it was once thickly mantled by the sherd-strewn soil that now forms a goodly part of the great talus heaps below.

There is little wonder, then, that the party despaired of finding even a single relic when they had reached the top of the trail and looked about at the destruction wrought; and yet they had been on the summit only a few minutes when a sherd of pottery of very ancient type, much crackled by weathering, was found. This fragment is of plain grey ware, quite coarse in texture, with a dégraissant of white sand.

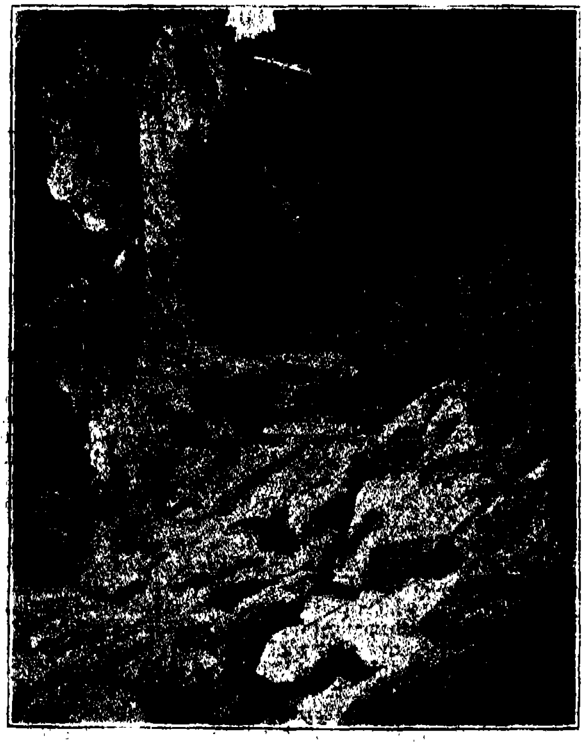

FIG. 2.—The Great Sandstone Cleft of the Mesa. Through this cleft the traditional trail passed, and distinct traces of it were found on each side of the vertical fissure to the right of the upper ladder.

During the twenty hours spent on the summit, every opportunity was taken of making a critical study of the general features of the top of Katzimo throughout the 2500 feet of its length, special consideration being devoted to the topography of the site, the erosion, the earthy deposits, the drainage, and the great cedars that stand gaunt and bare or lie prone and decaying because their means of subsistence have been so long washed away, and the party was forced to the conclusion that had house-walls, whether of stone or adobe, ever existed on the summit at a reasonably remote period, there was no possibility that any trace of them could have remained to this day. Nevertheless, the abundance of ancient relics in the talus, the distinct remains of the ladder-trail, the specimens found on the summit coupled with the destruction wrought by nature, the tradition itself—all testify to the former habitation of the site.

To the Acomas Katzimo is still enchanted, and as a subject in the study of mysticism the man of science must yet regard it. The law of a millennium is not undone by a few hours of iconoclasm.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—On March 15, Convocation will consider some alterations in the statute relating to the Aldrichian Demonstratorship in Comparative Anatomy, rendered vacant by the resignation of Dr. Blaxland Benham, who has been appointed Professor of Biology at Otago, New Zealand. Mr. Gilbert Bourne, of New College, has, in the meantime, been nominated as Lecturer in Comparative Anatomy, and his name will be submitted to Convocation on the same day.

Dr. Benham will be entertained at a farewell dinner by his colleagues on Friday.

The Junior Scientific Club met on Wednesday evening, March 9. Mr. A. W. S. Fisher read a paper on the salmon, and Mr. T. Annandale discussed the habits of British Amphibia. The officers for next term were elected. The Club proposes to hold its biennial conversazione next term, and arrangements are being pushed forward rapidly.

The cast of the skeleton of Iguanodon, which has been purchased by subscription, has now been set up in the court of the University Museum. Some valuable casts of other fossil reptiles have also been recently added to the collections.

CAMBRIDGE.—The honorary degree of Doctor of Science is to be conferred on Dr. Wilhelm Pfeffer, Professor of Botany in the University of Leipzig, and Croonian Lecturer at the Royal Society.

The Agricultural Examinations Syndicate report that ten candidates presented themselves for Part I., and nine for Part II. of the Examination for the diploma of the University. Six candidates were successful in both parts. The numbers show some increase on those of past years.

Regulations for the Gedge Prize in Physiology, taken in a broad sense, have been published. The prize will be given biennially for an original memoir or essay, and will consist of two years' interest on the capital sum of 1000*l*. Candidates must have worked in the University laboratories during six terms, and be of at least five, and at most seven, years' standing from matriculation.

The application for the recognition of St. Edmund's Hostel as a place of residence for students preparing for the secular priesthood of the Church of Rome, led to an animated discussion in the Senate on March 3. The weight of opinion was in favour of granting the application.

THE Senatus Academicus of the University of Edinburgh have resolved to offer the honorary degree of Doctor of Laws to Mr. Horace T. Brown, F.R.S.

PRESIDENT CHARLES DE GARMO, of Swarthmore College, Pa., has been elected to the professorship of the science and art of education at Cornell University, rendered vacant by the resignation of Prof. S. G. Williams; and Prof. Herbert Hibbard, of the University of Minnesota, has been elected assistant professor of mechanical engineering of railways and principal of the graduate school of railway, mechanical engineering.

NEARLY 55 per cent. of the net total of the Estimates for Civil Services, agreed to by the House of Commons on March 3, arises under the class of education, science and art, which shows a net increase of 457,094*l*. over the grants of last Session. To the total of the class—viz. 11,965,796*l*.—the three Public Education Estimates contribute 11,028,776*l*., being a net increase of 425,903*l*. The chief remaining increase is 22,663*l*. under the Science and Art Department Estimate (mainly for additional payments to science schools for attendance and on results). An important change has been effected in transferring to the Education Departments, England and Scotland, the grants, &c., for drawing in elementary schools, hitherto borne on the Science and Art Department's Vote, and in transferring to the Scotch Education Department the other Science and Art grants in Scotland.

A NOTEWORTHY feature of the little volume of announcements of classes held in the Northampton Institute, Clerkenwell, is a table of special courses adapted to various classes of students. By referring to this table, any young artisan can see what courses he ought to take to educate himself in the scientific principles of his trade. Similar guides to study, now often inserted in the prospectuses of technical institutes, are of great value in inducing students to take up systematic courses of instruction, and the Northampton Institute has done well to adopt such a means of encouraging earnest work. The Lord Mayor and Sheriffs have consented to pay a State visit to the Institute on March 18, for the purpose of inspecting it and declaring it formally open. The buildings and equipment have up to the present cost over 80,000*l.*, and the expenditure upon the latter is not yet complete. In addition the land—over one and a quarter acres—generously given by the late Marquis of Northampton, is estimated to be worth not less than 25,000*l.* The Institute is a branch of the City Polytechnic, and is situated in one of the busiest parts of the metropolis immediately north of the City boundary.

FROM the sixth annual report of the Technical Instruction Committee of the City of Liverpool, we gather the following items:—The Committee clearly recognises that technical education is inseparably bound up with general secondary and higher education, and must be organised in vital connection therewith.—After some delay, a commencement has been made with the erection of the new Central Technical Schools. The cost of the erection of the building comprising the new schools and the museum extension will be nearly 90,000*l.*—The Committee remark that it would be more satisfactory if greater attention were paid to mensuration and other practical applications of elementary mathematics; since it is a frequent complaint, on the part of teachers of special technical classes, that their students come to them with too little mathematical knowledge and aptitude, and are often unable to grapple with even simple quantitative problems. This difficulty not only applies to Liverpool, but to technical classes in most parts of the country.—The co-operation of the University College with the educational work of the Committee is most satisfactory, and is of great assistance in the construction of an organised scheme of technical instruction.

THE London University Commission Bill was read a second time in the House of Lords on Friday last. In moving the second reading, the Duke of Devonshire pointed out that the measure was founded on the recommendations of the Royal Commission which reported in favour of the two functions of teaching and examining being combined in one University for London. The Bill is substantially the same as that which passed the House of Lords in the last Session of Parliament, but reached the House of Commons too late to be carried through all its stages. To provide against the occurrence of a similar difficulty, the Bill has been introduced earlier in the year than has hitherto been found possible; which gives grounds for the hope that it will take its place on the Statute-book before the close of the present Session. A very large part of the formidable opposition against the Bill has been removed by the introduction of certain modifications. These amendments are in the direction of restricting the power of any future Senate to alter the statutes or regulations made by the Statutory Commission in accordance with the provisions contained in the schedule of the present measure. "I cannot even now assert that opposition no longer exists," said the Duke of Devonshire, "but it is very difficult indeed to understand upon what grounds the measure can be opposed. I have endeavoured to show by what an overwhelming amount of scientific teaching, opinion, and experience it is supported, and I am utterly unable to discover any weight of opinion on the other side which can for a moment enter into competition with the expressions in its favour." Lord Herschell and Lord Reay warmly supported the Bill, which was then read a second time

AT the recent meeting of the Federated Institution of Mining Engineers, Prof. Henry Louis, Durham College of Science, Newcastle, read a paper on "Technical Education in Mining," which should be seen by all Technical Education Committees having mining classes. Prof. Louis made, at the outset, a broad distinction between the training suitable to the working miner or subordinate mine official, and that suitable to mining engineer or general manager. As regards the former he ought to leave his Board school in about the fifth standard, and commence receiving his technical instruction—a very different thing from technical education—underground, whilst continuing his scientific education in evening continuation and science schools. It is greatly to the discredit of the powerful and wealthy miners' unions of this country, that they make no attempt to provide the rising generation with scientific training bearing on their work, especially seeing that such training is the best possible safeguard against accident. For both working miners and engineers, the present legislation, that takes no account of time spent in learning the sciences underlying the art of mining, is most pernicious. Mining students ought to enter some mining college at the age of seventeen, and devote at least three years to learning first the pure and then the applied sciences that they will require in their profession, but none of the pure sciences need to be studied very profoundly. The systematic neglect of the study of dressing of minerals in this country has already had serious commercial results, *e.g.* at Nenthead, and its cultivation is urged. Prof. Louis suggests the introduction of the American system of "Summer Mining Schools" as a method worthy of trial for giving college students an insight into practical work, but points out that college work alone without practical experience is insufficient. On the very open question as to whether college work should precede or follow practical training, Prof. Louis holds the former to be probably the better plan. He concludes with the following recommendations. (1) Every manager of a mine, whether coal or metalliferous, to hold a certificate. (2) Examinations for certificates to be controlled by a central Board, and made uniform in conditions and character for the whole of Great Britain (and if possible for the Colonies also) (3) Residence in a recognised science college to count as part of term of apprenticeship, whilst not less than three years underground should also be insisted on. (4) Every mine surveyor to hold a certificate of proficiency.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 27.—"Mathematical Contributions to the Theory of Evolution. On the Law of Ancestral Heredity." By Karl Pearson, F.R.S., University College, London.

The Darwinian theory has for its main factor the perpetuation of favourable variations by natural selection under the law of heredity. Hence any complete quantitative treatment of evolution must deal (1) with the nature and distribution of variation; (2) with the nature and influence of selection, and this not only upon the selected but upon all correlated characters or organs; and (3) with the law of heredity. Earlier published and other written but unpublished papers of the present writer cover to some extent the ground of (1) and (2). Although the mathematical theory of variation and selection is yet very far from completion, the general lines on which it will proceed seem fairly clear. With the law of heredity, however, the case has hitherto been different. Much has been written on the subject, much has been attributed to inheritance, but the quantitative measurements and facts have formed such a small and slender proportion of the whole, that it has been extremely difficult to base a rounded mathematical theory on what is really known.

The very suggestive theory of heredity developed in Mr. Galton's "Natural Inheritance" has two main features: (*a*) a theory of regression, which states the average proportion of any character which will be inherited under any degree of relationship. This theory is very simple: if the average of the sons of any parent has w of the parent's deviation from the average parent, then the average grandson would have w^2 of the deviation, and so on. Collateral heredity is also determined, and for two brothers was found equal to $2w$. Mr. Galton's value of w was $\frac{1}{3}$.

(*b*) A law of ancestral heredity. According to this law the two parents contribute $\frac{1}{2}$, the four grandparents $\frac{1}{4}$, the eight great grandparents $\frac{1}{16}$, and so on, of the total heritage of the average offspring.

These two parts of the theory, however, are not in entire agreement.

The recent publication of Mr. Galton's remarkable paper on ancestral heredity in Bassett hounds has, however, led the writer to reconsider (*b*). If that law be true, then for every organ and for every grade of kinship the amount of heredity is numerically determinable. The solution of the problem of heredity is thrown back upon the solution of an infinite series of linear equations. Their solution gives results which seem to the writer in good agreement with all we at present know about the influence of heredity in various degrees of kinship. For example, fraternal is no longer *twice* filial regression, but has a value (0·4000) well in accordance with calculations of English stature and Indian cephalic index. In short, if we discard Mr. Galton's relations between the regressions for various grades of kinship, and start solely from his law of ancestral heredity, the whole theory of heredity becomes simple, luminous, and well in accordance with such quantitative measurements as have so far been made.

It is possible to somewhat generalise the law of ancestral heredity. Modifying Mr. Galton's definition of midparent, a conception is formed of the mid-sth parent, a sort of mean of the ancestry in the sth generation, and the contribution of this mid-sth parent to the offspring is assumed to have a constant ratio to that of the mid-$(s + 1)$th parent, whatever be the value of s. With this simple law the whole of heredity is found to depend upon a single constant γ, termed the *coefficient of heredity*. γ may vary from organ to organ and from race to race. It may itself be subject to selection, if heredity be not looked upon as *à priori* given and antecedent to any evolution by natural selection. In Mr. Galton's statement of the law, $\gamma = 1$. This may really be the case, but it is not necessary to the theory, and it is not required by any facts as yet observed.

Given this simple law of ancestral heredity, there flow from it the following results :—

(1) Heredity between any grade of individual kinship.

(2) The value of the stability that results from any long or short process of selective breeding, and the variability of the breed so established.

(3) The law of cross heredity, *i.e.* the degree of relationship between two *different* organs in kindred.

(4) That panmixia without active reversal of natural selection does not lead to degeneration.

It may be of interest to add that since the law of ancestral heredity allows for the variability of each individual ancestor from the ancestral type, giving that variability its share in the heritage of the offspring, it is inconsistent with Weismann's theory of the germplasma. It does not, of course, answer one way or the other the question as to the inheritance of acquired characters.

Thus Galton's law of ancestral heredity leads to, what has not hitherto existed, a rounded and comprehensive theory of heredity. It describes with surprising closeness all facts so far quantitatively determined, and opens up a wide range of conclusions which await testing by fresh data. Should those data be in agreement with its predictions, then the law of ancestral heredity will in the future play as large a part in the theory of evolution as the law of gravitation has played in planetary theory. It is the quantitative basis on which Darwinism, the evolution of species by natural selection *combined with heredity*, will then be placed ; and at one stroke it will clear away a veritable jungle of semi-metaphysical speculations and hypotheses, and this for the simple reason that it is based upon quantitative observations and not on verbal subtleties. It will be difficult, perhaps, to make people realise that there is a science of heredity, simple and consistent, in existence ; yet even at the present time it is the number of observers and experimenters, rather than the science, which needs to be strengthened.

"The Magnetic Properties of almost pure Iron." By Ernest Wilson.

In the Siemens Laboratory, King's College, London, a series of experiments were carried out on a ring of iron containing only about ·12 per cent. impurities. The ring was tested as received and after careful annealing. As received, the magnetic hysteresis loss was slightly greater than in an exceptionally good sample of transformer plate examined by Ewing. After annealing the hysteresis loss was still slightly inferior to the Ewing specimen, but an exceptionally large value was obtained for its maximum permeability ; μ being 5490 for $B = 9000$ C.G.S. units per square centimetre. The coercive force for maximum $B = 15{,}720$ is 1·13 C.G.S. units. Further experiments were carried out to investigate the apparent magnetic instability of the specimen. The author finds that this effect cannot be accounted for by the self-induction of the ring, nor the time taken for the current to rise to its full value. A method is explained for testing the rapidity with which the current rises to its maximum value. The propagation of magnetism in the ring as affected by induced currents is dealt with, and it is pointed out that these may have an effect on the observations, although it is difficult to account for such times as five and ten seconds, unless the molecule itself be considered. It is deduced from the experiments that the amplitude of induction might not be so great for high frequency and small induction density, which would be of importance in the case of transformer cores if it existed. Reference is made to experiments with alternate currents which show no such diminution ; but it is pointed out that experiments with alternate currents would be difficult to carry out, on account of the necessary accurate control of the magnetising force.

"The Kelvin Quadrant Electrometer as a Wattmeter and Voltmeter." By Ernest Wilson.

Two of these instruments were available to the author when carrying out the series of tests described in this paper. He was thus able to use one in connection with a revolving contact-maker to determine the instantaneous rate at which work was being done by alternate currents while testing the other as a direct-reading wattmeter. The author finds that by the contact-maker method he gets good accuracy by taking ten positions of the contact-maker per half-period, and calculating directly from the figures without integrating the curves. When current and potential were in phase an agreement within 1 or 2 per cent. was obtained between the watts calculated this way and the product of the square root of mean square values given by an ammeter and voltmeter. The use of a small mallet for gently tapping the electrometer base is recommended to overcome the effects of viscosity of the acid in the electrometer when this is old, although in the new form of instrument the viscosity gives little or no trouble, since the sensibility is not so great. The wattmeter constant was determined for various frequencies, phase differences, amplitudes, wave forms, and the results show that the Kelvin quadrant electrometer can be used with accuracy as an alternate current wattmetter, but that it is necessary to make sure that within the range of potentials applied Maxwell's formula is verified. Two methods of doing this are explained. The author observed a potential of nearly half a volt, due to the revolving contact-maker alone, when directly placed across the electrometer ; but this inductive effect disappeared when a capacity, large compared to that of the instrument, was placed across it. The paper concludes with an interesting note on a manganin strip used for comparatively large currents. The experiments were carried out in the Siemens Laboratory, King's College, London.

February 3.—"The Pharmacology of Aconitine, Diacetylaconitine, Benzaconine and Aconine, considered in relation to their Chemical Constitution." By J. Theodore Cash, M.D., F.R.S., and Wyndham R. Dunstan, M.A., F.R.S.

In this research the pure alkaloids aconitine, benzaconine and aconine derived from *A. Napellus*, and an aconitine derivative, diacetylaconitine were examined with reference to their action upon warm- and cold-blooded animals, a similar series of experiments being made with each alkaloid for purposes of contrast.

It was found if the dose of aconitine, which is invariably lethal per kilo. body weight, be represented by the unit, that (in very general terms) diacetylaconitine would have $\frac{1}{40}$" of the toxicity of aconitine, benzaconine $\frac{1}{300}$, and aconine $\frac{1}{3000}$. There is, therefore, an enormous variation in toxicity amongst these alkaloids.

A few of the chief results obtained are here summarised.

Aconitine in small doses slows the pulse, whilst larger proportions not only accelerate but disturb the sequence of ventricles upon auricles—an independent rhythm being produced at one stage of action. The central vaso-motor apparatus is much more powerfully affected than the peripheral, great respiratory acceleration precedes slowing, which, according to the dose, may pass into failure. Sensory nerves are depressed in function, whilst motor-nerve terminations and skeletal muscle retain their activity, except when largely hyperlethal doses have been used.

Diacetylaconitine has less tendency to cause disturbance of sequence between auricles and ventricles ; but, apart from variations in this and other minor points, its action is in the main like that of aconitine.

Benzaconine alters the cardiac rhythm, the pulse becoming much slowed ; and at one phase of action the sequence of ventricle fails to every second auricular beat. Entire suspension of contraction may even occur, both auricles and ventricles, followed by spontaneous resumption of systole. Respiration is slowed from the first.

Sensory nerves are but little affected, whilst motor-nerve endings and, to a lesser degree, skeletal muscle show a reduced and curiously intermittent response to stimulation.

Aconine strengthens the cardiac systole, and is opposed to the dislocation of rhythm produced by aconitine, to which it therefore acts in a large measure as an *antagonist* and *antidote*. On motor-nerve termination it has a curare-like effect.

All the alkaloids examined reduce body temperature, though in varying degree.

In conclusion it is pointed out that, whilst the toxicity of aconitine mainly depends on the presence of the acetyl group, the introduction of two additional acetyl groups into the aconitine molecule does not materially alter the pharmacological action, but merely reduces the toxicity of the parent alkaloid. The *removal* of the acetyl group abolishes the stimulant action upon the respiratory centre and pulmonary vagus. It also favours reduced activity in motor, rather than in sensory nerve endings.

The benzoyl group—present in benzaconine, absent in aconine—causes a peculiar and distinct modification in the heart's action, associated with a disturbance of sequence never witnessed after aconine. The curare-like effect of aconine, and the intermittent failure of the stimulated benzaconine muscle, are also traceable to the modification in chemical constitution arising from the absence or presence of the benzoyl group.

Attention is drawn to the practical bearing of the fact that benzaconine and aconine, pharmacological antagonists of aconitine, occur with it in the root of *Aconitinum Napellus*, from which the medicinal preparations of the drug are made.

February 10.—"Contributions to the Theory of Alternating Currents." By W. G. Rhodes, M.Sc. (Vict.).

This paper was divided into two parts. Part I. dealt with a method of finding the steady values of alternating currents in any circuits or systems of circuits, without having to perform integrations of differential equations which may be somewhat complicated.

Part II. was devoted to the consideration of the effects of higher harmonics in E.M.F.s and currents on the values of the impedances and reactances of circuits.

Among other results it was shown that periodic E.M.F.s and corresponding currents can in all cases be represented by simple sine curves having the same root mean square values, and suitable phase positions depending on the time constants of the circuits and on the periodicities of the harmonics present.

February 17.—"On Artificial Temporary Colour-Blindness, with an Examination of the Colour-Sensations of 109 Persons." By George J. Burch, M.A.

By exposing the eye to bright sunlight in the focus of a burning-glass behind a red screen, a condition of temporary red-blindness is induced during which scarlet geraniums appear black and roses blue. Green-blindness and also violet-blindness may be produced by similar means.

The author has systematically investigated the appearance of the spectrum during the colour-blindness induced by exposure to intense light from various parts of the spectrum, and finds that the red from A to B, the green near E, the blue half-way between F and G, and the violet at and beyond H, produce well-defined and characteristic results, indicating that each of these colours corresponds to a definite colour-sensation.

In each case all direct sensation of the colour used for fatiguing the eye is lost, but the observer is conscious of a positive after-effect of the same colour, by which the hue of all other colours is modified. The temporary abolition of any one colour-sensation is without effect on the intensity of the remaining colour sensations. Any two, or any three, of the four colour sensations, red, green, blue, and violet, can be simultaneously or successively exhausted. The observed facts are, in the author's opinion, more in accordance with the Young-Helmholtz theory than with that of Hering, but they imply the existence of a fourth colour-sensation, namely blue.

Physical Society, Feb. 26.—Mr. Shelford Bidwell in the chair.—The meeting was held at Eton College. The President informed the Society of the resignation of one of its Hon. Secretaries: Mr. T. H. Blakesley, M.A. In doing so, he referred to the many important services rendered to the Society by Mr. Blakesley, and he expressed the Society's deep and general regret that Mr. Blakesley should now feel unable to continue them. The Council elected Mr. W. Watson to the office of Hon. Secretary.—Prof. T. C. Porter, in whose laboratory the meeting was held, said it gave him very great pleasure to welcome the Physical Society. Eton had been most properly called "the English home of ancient classical learning." For the education of youth, classics had proved themselves of cardinal value. He believed that other Fellows of the Physical Society, *with himself, desired that this revered tradition of classics should be maintained at Eton; at the same time, they would agree* with him that there was no better supplement to classics than a fair knowledge of the natural sciences. Prof. Porter then gave a lecture, illustrated by lantern photographs, on "*Observations on the Peak of Tenerife.*" He also described his method for measuring the diameter of the earth. The method consists in observing the shadow cast by the Peak upon the sea, and measuring the time that elapses between the moment when the apex of the shadow touches the sea-horizon, and the instant when it is eclipsed by the shadow of night. Prof. Porter called attention to a phenomenon hitherto unnoticed, *i.e.* that the heated air ascending from the Peak casts a shadow, seen as a faint prolongation of that of the Peak; it rises obliquely from its apex. A photograph was exhibited, taken on a quarter-plate, in which is visible the curvature of the horizon as viewed from the altitude of the Peak. An interesting series of unique photographs, illustrating the conformation of the Peak and the phenomena of sunrise and twilight in that latitude, was also shown. In regard to twilight he noticed that the first approach of night, as observed looking eastward, is marked by a dark border of about five degrees width, followed by a sky somewhat lighter. The lecturer discussed also a new theory of geyser action. The theories of Bunsen and others fail to explain why *the geyser-throat appears almost completely full at the end of* an eruption. This immediate refilling is the more remarkable when it is remembered that some geysers of the Yellowstone region discharge a *million* and a *half* gallons at each eruption, and that the eruptions may occur at five-minute intervals. Moreover, the theories generally accepted assume steeper temperature-gradients than those in a region like Yellowstone. Prof. Porter suggests that the phenomena are better explained on the assumption of an arrangement of strata such as exists in artesian-well districts, the throat or shaft of the geyser being in the position of a well communicating with a subterranean stream—the "tube" of the geyser. From the disturbed nature of the region the tube of the geyser follows a waved course; the "shaft" rises from the crest of the terminal wave; the other crests may be steam-traps. Since a basin-like formation is characteristic of all geyser regions, it is fair to assume that the end of the tube remote from the shaft has an outcrop in the hills that form the sides of the basin. By means of this outcrop, water continually flows into the tube. When the tube does not sink deeply enough to attain the temperature necessary for the generation of steam, a quietly-flowing hot-spring is the result. But if, at any point, the tube descends to underground temperatures sufficiently great, steam is formed, and is trapped at the highest point of a bend. Ultimately this steam checks the flow of water, until the accumulated head of cool water from the hills overcomes the resistance, condenses the steam, and re-establishes liquid continuity. *Urged by the pressure behind it*, the stream is impelled towards the geyser throat; it forces the hot water before it until equilibrium is once again restored in the tube. Prof. Porter afterwards exhibited a method for viewing lantern projections in stereoscopic relief. A slotted disc rotates in front of two lanterns. These project two stereoscopic views in rapid alternation upon a screen, in such a way that the two projections are approximately superposed. In the rim of the disc, other slots are cut, through which the observer looks. The arrangement of slots is such that the right or left eye is only able to see the screen at the moment when its own picture (*i.e.* the picture from the right or left lantern) is on the screen. When the rotation is sufficiently rapid, the views appear as one, without "flicker," in stereoscopic relief.—The President proposed votes of thanks, and the meeting was adjourned until March 11.

Entomological Society, February 16.—Mr. G. H. Verrall, Vice-President, in the chair.—Mr. G. C. Champion exhibited specimens of *Isodermus gayi*, Spin., from the Straits of Magellan, and *I. planus*, Er., from Tasmania, both found by Mr. J. J. Walker. The genus, *Isoderma*, belonging to the Aradidæ, afforded an interesting case of geographical distribution, the only known species occurring in Chili, Australia and Tasmania.—Mr. C. O. Waterhouse referred to the similar distribution of other species of insects, which went to support the theory of a former connection between South America and Australia.—Mr. Champion also showed an example of *Bagous lutosus*, Gyll., from Sweden. This insect had been on the British list since the time of Stephens, but possibly in error, as all the examples he had seen in collections were wrongly so named.—Mr. Jacoby exhibited a pair of the singular weevil, *Apoderus tenuissimus*, Pasc., from the Philippines.—Mr. Burr exhibited species of Orthoptera, of the family Eumastacidæ, resembling dead leaves. This was the only family of Acrydiidæ in which such resemblances were found.—Dr. Chapman exhibited a specimen of *Zygæna exulans* with six wings, the supernumerary pair arising between the normal left forewing, and the corresponding leg on the same side. The uppermost wing appeared normal in every respect, the second was a reduced copy of the basal half of a forewing, and the third a portion of crumpled wing-structure.—Mr. O. E. Janson exhibited a pale variety of the rare *Papilio mikado* taken in South Japan.—Mr. Tutt showed a variety of *Enodia hyperanthus*, taken by Mr. F. H. Day near Carlisle, and banded on the underside like a *Cœnonympha*; also two moths from the same neighbourhood, which, after careful comparison, he regarded as females of *Hydrilla palustris*. This sex was almost, or quite, undiscovered in Great Britain, and the occurrence of the species so far from the fen-district was remarkable.—Mr. H. J. Elwes read a paper, entitled "A Further Revision of the Genus *Erebia*," which was illustrated by the exhibition of examples of every known species. Tracing the geographical distribution, he stated that the principal European centres of the genus were the Pyrenees, and especially the Alps, only a few forms occurring in Scandinavia, while the Ural Mountains and Caucasus were almost destitute of species. The genus became abundant in East Siberia, from which region the few North American forms appeared to have been derived.—Dr. Chapman also read a paper on the species of the genus *Erebia*, a revision based on the male appendages, illustrated with drawings of these organs in about sixty species.—In connection with the above papers Mr. Tutt exhibited and made remarks on long series of *Erebia nerine*, *E. glacialis*, *E. euryale*, *E. ligea*, &c., chiefly from the Alps.

PARIS.

Academy of Sciences, February 28.—M. Wolf in the chair.—Chemical action of the silent discharge: oxides of carbon and nitrogen, by M. Berthelot. A continuation of a previous paper. Mixtures of carbon monoxide and nitrogen, submitted to the prolonged action of the silent discharge, give only the sub-oxide C_4O_3, the nitrogen being unchanged. With excess of hydrogen, a condensation product of the empirical formula $(CH_2O)_n$ is produced. For carbon dioxide, six hours' action with hydrogen in excess caused the almost complete absorption of the oxide. With nitrogen in addition an amido-compound and some ammonium nitrite were formed.—Chemical action of the silent discharge: alcohols and etherial derivatives in presence of nitrogen, by M. Berthelot. The systems studied were mixtures of nitrogen with methyl alcohol, ethyl alcohol, normal propyl, isopropyl and allyl alcohols, phenol, pyrocatechol, resorcinol, hydroquinone, pyrogallol, glycol, and methyl and ethyl ethers.—Fuchsian functions and the equation $\Delta u = e^u$, by M. H. Poincaré.—On a particular case of the motion of liquids, by M. E. Fontaneau.—On the Euler transformation and the determination of singular points of a definite function by Taylor's development, by M. Ernst Lindelöf.—On an extension of Gauss's method of quadrature, by M. Henry Bourget.—On autocollimating telescopes, and an optical verifier of the lines and surfaces of machines, by M. Ch. Dévé. The arrangement described, which is illustrated by three diagrams, permits of the exact verification of the accuracy of plane surfaces, or of the parallelism of two surfaces.—Lines of force and equipotential surfaces in nature, by M. G. M. Stanoiévitch. The paper is illustrated by three plates showing the analogy between the lines of growth in plants and equipotential surfaces. The nodes in the wood play the part and produce the same disturbances in the cellular field as magnetic or electric poles in their respective fields.—On the properties and crystallisation of anhydrous barium sulphide, by M. A. Mourlot. The crystallised sulphide was obtained in two ways: by submitting amorphous barium sulphide, previously prepared by the action of hydrogen sulphide upon barium carbonate at a red heat, to the temperature of the electric furnace, and by heating directly in the electric furnace a mixture of barium sulphate and carbon in the exact proportions necessary to form the sulphide. In this way white crystals belonging to the cubic system were obtained, which behave toward chemical reagents like the amorphous form, except that the action is somewhat slower in the case of the crystals. The behaviour of the sulphide towards fluorine, oxygen, and oxidising agents, phosphorus oxychloride, and carbon was studied.—Action of carbon monoxide upon palladious chloride, by M. E. Finck. By the interaction of these two substances three compounds can be isolated, $COPdCl_2$, $C_2O_2PdCl_2$ and $C_3O_3Pd_2Cl_4$, corresponding to the analogous platinum compounds.—On hydrocinnamide, by M. Marcel Delépine. The crystallised hydrocinnamide has the composition $2C_{27}.H_{24}.N_2.H_2O$, and possesses the properties of the glyoxalidines. It is a base forming stable salts, and the name cinnamine is proposed as more suitable than hydrocinnamide.—On an oxyptomaine, by M. Œschner de Coninck. The pyridic ptomaine described in an earlier paper, and which possesses the composition of a collidine, is easily oxidised by hydrogen peroxide to an oxycollidine,

$$C_8H_{10}(OH).N,$$

from which the original base can be regenerated by distillation with zinc-dust.—On the oxidation of sorbite to sorbose, by M. Gabriel Bertrand. An examination of the experiments of M. Matrot upon the same subject, according to which sorbose is produced whatever ferment be employed in the oxidation. This result is controverted in the present paper, the method of oxidation used by M. Matrot, in which the cultures are exposed to contamination by air organisms, being the cause of the effects observed.—On the preparation of white wines from red grapes, by M. V. Martinand. The fermentation is interrupted by cooling, and the colour removed by aëration of the liquid. After filtration from the solid deposit, the fermentation is completed.—On the influences of intermittent rest and work upon the mean power of a muscle, by MM. André Broca and Charles Richet. When the load on the muscle is below a certain limit, intermittent repose is harmful; for moderate loads, without any effect; and with still greater weights, favourable to the production of work.—Evolution and structure of the conjunctive elements in *Paludina*, by M. Joannes Chatin.—The dissociation of the egg in a large number of distinct individuals, and the cycle of evolution in *Encyrtus fuscicollis*, by M. Paul Marchal.—On optical anomalies and polymorphism, by M. Fréd. Wallerant.—Contribution to the geology of Lower Sénégal, by M. Stanislas Meunier.

AMSTERDAM.

Royal Academy of Sciences, January 29.—Prof. van de Sande Bakhuyzen in the chair.—Prof. Jan de Vries, on some groups of circles. Construction of a system of n lines, forming (n_3) triangles, whose circumscribed circles pass through the same point. Inversion of a quadrilateral and its four circles into a spherical configuration of eight points and eight circles. The analogous spherical configuration 16_6 in connection with Miquel's theorem on the pentagon.—Prof. Martin exhibited a new crystalline form of gold, a perfect tetrahedron, found in Brazil. On the ground of the existence of this crystal the speaker considered hemihedrism of gold possible, though not proved by this single specimen.—Prof. Kluyver presented a paper, entitled "On the binominal development," dealing with the Rev. Simmons's New Theorem in Probability (*Proceedings* of the London Mathematical Society, 1895, p. 290). A method of investigation entirely different from that used by the Rev. Simmons enabled the author to confirm the results arrived at by the latter, concerning the "complete sets" of trials. As for the "broken sets," the same method led to a first approximation of the "advantage," from which it was possible to derive the conditions that must be satisfied, if the probability of net gain is to exceed the probability of net loss.—Prof. Jan de Vries presented, on behalf of Dr. G. de Vries, of Haarlem, a paper entitled "Le tourbillon cyclonal." By this the author means a vortex, which is at the same time both a ring vortex and a columnar vortex, in which, consequently, motion takes place along spirals. After deducing the equations of motion in cylindrical coordinates, a general solution is given, through which a differential equation for the current function is arrived at.—Prof. Moll presented, on behalf of Mr. J. H. Bonnerra, of Leeuwarden, a paper entitled "Sedimentary Erratics of Kloosterholt" (Heiligerlee). The erratics treated of in this paper have been gathered from boulder-clay. While the sedimentary erratics from Groningen bear a great resemblance to certain strata in the Russian Baltic provinces, those of Kloosterholt are more like certain Swedish rocks. As regards their geological age, most of them must be classed with the Silurian and the Chalk formation, while Cambrian Jurassic and Tertiary formations are more sparingly represented.

DIARY OF SOCIETIES.

THURSDAY, MARCH 10.

ROYAL SOCIETY, at 4.30.—(1) On the Rotation of Plane of Polarisation of Electric Waves by a Twisted Structure. (2) On the Production of a "Dark Cross" in the Field of Electro-magnetic Radiation: Prof. J. C. Bose.—An Extension of Maxwell's Electro-magnetic Theory of Light to include Dispersion, Metallic Reflection, and Allied Phenomena: E. Edser.—On the Relative Retardation between the Components of a Stream of Light produced by the Passage of the Stream through a Crystalline Plate, cut in any Direction with respect to the Faces of the Crystal: J. Walker.—On the Relation between the Diurnal Range of Magnetic Declination and horizontal Force, and the Period of Solar Spot Frequency: W. Ellis.

ROYAL INSTITUTION, at 3.—Recent Researches on Magnetism and Diamagnetism: Prof. J. A. Fleming, F.R.S.

SOCIETY OF ARTS (Indian Section), at 4 30.—India and Sir Henry Maine: Charles Lewis Tupper, C.S.I.

MATHEMATICAL SOCIETY, at 8.—The Geodesic Geometry of Surfaces in non-Euclidean Space: A. N. Whitehead.—The Transformation of Linear Partial Differential Operators by Extended Linear Continuous Groups: Prof. Elliott, F.R.S.—Stereographic Illustrations of Catenaries: Prof. Greenhill, F.R.S., and T. I. Dewar.—On Linear Homogeneous Continuous Groups whose operations are Permutable: Prof. W. Burnside, F.R.S.—Supplementary Note on Aurifeuillians: Lieut.-Colonel Cunningham, R.E.—On the Calculation of the Sum of the *m*th Powers of a Large Number of Magnitudes: W. F. Sheppard.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—On the Manufacture of Lamps and other Apparatus for 200 volt Circuits: G. Binswanger-Byng.

FRIDAY, MARCH 11.

ROYAL INSTITUTION, at 9.—Marked Unexplored: W. F. Lord.

ROYAL ASTRONOMICAL SOCIETY, at 8.—On a convenient Method of Adjusting a Polar Axis to the Diurnal Motion: D. P. Todd.—Nebulæ discovered at the Royal Observatory, Cape of Good Hope: Royal Observatory, Cape of Good Hope.—List No. 7 of new Nebulæ: L. Swift.—Long enduring Spots on Jupiter: A. S. Williams.—The Concave Grating for Stellar Photography: C. L. Poor.—On the Fallacy Associated with the Current Rotation Periods of Venus: E. M. Antoniadi.—Equatorial Comparisons of Neptune with 114 Tauri: J. Tebbutt.—A Remarkable Object in Perseus: Rev. T. E. Espin.—On the "Two Method" Personal Equation: W. W. Bryant.—A few Suggestions with Reference to the Newtonian Reflector: T. W. Bush.—The Spectrum of *o* Ceti, as Photographed at the Stonyhurst College Observatory: Rev. W. Sidgreaves.—The Effect of Latitude Variation on the Ecliptic Investigation: W. G. Thackeray.—Note on Dr Gill's Paper on the Effect of Chromatic Dispersion of the Atmosphere on the Parallaxes of α Centauri and β Orionis: Prof. A. A. Rambaut.

PHYSICAL SOCIETY, at 4.—Council Meeting.—At 5.—On Dynamical Illustrations of certain Optical Phenomena: Prof. J. D. Everett, F.R.S.—On Properties of Liquid Mixtures: R. A. Lehfeldt

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Drainage of Cottage Property: H. C. Adams.

MALACOLOGICAL SOCIETY, at 8.—The Mollusca of Lake Tanganyika, with especial reference to their Origin and Affinities: J E S. Moore.—On the Anatomy of *Mulleria* and *Mutela*: M. F. Woodward.

MONDAY, MARCH 14.

SOCIETY OF ARTS, at 8.—The Thermo-Chemistry of the Bessemer Process: Prof. W. N. Hartley, F.R.S.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Exploration in Spitsbergen, 1897: Sir W. Martin Conway.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Electrical Industries at the Foyers Waterfalls: R. W. Wallace.

TUESDAY, MARCH 15.

ROYAL INSTITUTION, at 3.—The Simplest Living Things: Prof. E. Ray Lankester, F.R.S.

SOCIETY OF ARTS (Foreign and Colonial Section), at 4 30.—The West Indies and Sugar Bounties: Nevile Lubbock.

ZOOLOGICAL SOCIETY, at 8.30.—On New or Imperfectly Known Species of Ostracoda, chiefly from New Zealand: Dr. G. Stewardson Brady, F.R.S.—On a New Flagellate Protozoan of the Genus *Lophomonas*: E. H. J. Schuster.—On the Early Post-Larval Stages of the Crab (*Cancer pagurus*), and on the Affinity of that Species with *Atelecyclus heterodon*: J. T. Cunningham.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Calcium Carbide and Acetylene: Henry Fowler.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—*Half-tone Negative-making*: W. H. Lascelles.

ROYAL VICTORIA HALL, at 8.30.—Wireless Telegraphy: A. W. Porter.

ROYAL STATISTICAL SOCIETY, at 5.

WEDNESDAY. MARCH 16

SOCIETY OF ARTS, at 8.—The Recent History of Paper-making: Clayton Beadle.

ROYAL GEOGRAPHICAL SOCIETY, at 4.30.—Sea Beaches and Sand Banks: Vaughan Cornish.

ENTOMOLOGICAL SOCIETY, at 8—Further Notes on Dyscritina, Westw.: E. E. Green.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Photographing Meteorological Phenomena: Arthur W. Clayden.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Exhibition of Mounted Rotifers: G. F. Rousselet.

THURSDAY, MARCH 17.

ROYAL SOCIETY, at 4.30.—The Croonian Lecture will be delivered by Prof. Wilhelm Pfeffer, For. Mem. R.S. On the Nature and Significance of Functional Metabolism (Betriebs-stoffwechsels) in the Plant

ROYAL INSTITUTION, at 3.—Magnetism and Diamagnetism: Prof. J. A. Fleming, F.R.S.

LINNEAN SOCIETY, at 8.—Natural Selection the Cause of Mimetic Resemblance and Common Warning Colours: Prof. E. B. Poulton, F.R.S.—On the Brain of the Edentata, including Chlamydophorus: Dr. Elliott Smith.—On Limnocarpus, a New Genus of Fossil Plants from the Tertiary Deposits of Hampshire: Clement Reid.

CHEMICAL SOCIETY, at 8.—The Reduction of Bromic Acid and the Law of Mass Action: Winifred Judson and Dr. J. Wallace Walker.—The Action of Ferric Chloride on the Ethereal Salts of Ketone Acids:—Dr. R. S. Morell and Dr. J. M. Crofts.—Note on the Volatility of Sulphur T. C. Porter.—Action of Ammonia and Substituted Ammonias on Acetylurethane: Dr. George Young and Ernest Clark.—Cannabinol: T. B. Wood, W. T. N. Spivey, and Dr T. H. Easterfield.—Formation of Oxytriazoles from Semicarbazides: Dr. G. Young, and B. M. Stockwell.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Sixth "James Forrest" Lecture, Geology in Relation to Engineering: Prof. W. Boyd Dawkins, F.R.S.

CAMERA CLUB, at 8.15.—Some Recent Animal Photographs: Gambier Bolton.

FRIDAY, MARCH 18.

ROYAL INSTITUTION, at 9.—The Bringing of Water to Birmingham fro the Welsh Mountains: J. Mansergh.

BOOKS, PAMPHLET, and SERIALS RECEIVED.

BOOKS.—Peregrinazioni Antropologische e Fisiche, &c.: Dr. T. Vignoli and Prof. G. V. Schiaparelli (Milano, Hoepli).—Travels in the Coastlands of British East Africa &c.: W. W. A. Fitzgerald (Chapman).—L'Algérie: J. A. Battandier and L. Trabut (Paris, Baillière).—Epidemic Diphtheria: Dr. A. Newsholme (Sonnenschein)—Magnetical and Meteorological Observations made at the Government Observatory, Bombay, 1896 (Bombay).—Geological Literature added to the Geological Society's Library during the Year ended December 31, 1897 (Geological Society).—Royal Geographical Society. Year-Book and Record, 1898 (Royal Geographical Society).—La Photographie et l'Étude des Nuages: J. Boyer (Paris, C. Mendel).—The Teacher's Manual of Object-Lessons in Domestic Economy, V. T. Murché: Vol 1 (Macmillan).—General Elementary Science (Clive).

PAMPHLET.—Review of Mineral Production in India for 1896 (Calcutta).

SERIALS.—Bulletin de l'Académie Royale des Sciences, &c., de Belgique, 1898, No. 1 (Bruxelles)—Journal of the Royal Microscopical Society, February (Williams).—Zeitschrift für Physikalische Chemie, xxv. Band, 2 Heft (Leipzig, Engelmann).—Middlesex Hospital Journal, Vol. 2, No. 6 (London).—Quarterly Journal of the Geological Society, February (Longmans).—Journal of Botany, March (West).—Scribner's Magazine, March (Low).—Archives de Parasitologie, January (Paris, Carré).—Revue de l'Université de Bruxelles, March (Bruxelles).—National Review, March (Arnold).—Fortnightly Review, March (Chapman).—National Geographic Magazine, February (Washington).—Transactions of the American Microscopical Society, December (Buffalo).—Geographical Journal, March (Stanford).—Astrophysical Journal, February (Chicago).—Atlantic Monthly, March (Gay).

THURSDAY, MARCH 17, 1898.

THE CHEMISTRY OF THE METALS.

A Treatise on Chemistry. By H. E. Roscoe and C. Schorlemmer. Vol. ii. The Metals. New edition completely revised by Sir H. E. Roscoe, assisted by Drs. H. G. Colman and A. Harden. Pp. 1192. (London: Macmillan and Co., Ltd., 1897.)

NEARLY twenty years have elapsed since the appearance of this part of Roscoe and Schorlemmer's well-known treatise, and as in the interval much important work has been done in connection with the classification of the elements, with metallurgical processes, with chemical manufactures and new theories bearing upon our views of the constitution of salts, the condition of dissolved substances and other important questions have been proposed, it is obvious that the time has come when a new edition is urgently needed. It may at once be said that the revision has been accomplished with great care, with full knowledge, and, speaking generally, with a great measure of success.

The introductory chapters, which occupy 150 pages, naturally contain the most debateable matters, concerning which, probably, there will always be considerable differences of opinion, relating as they do to such subjects as the characteristics of metals, to valency, to classification and other subjects which are less matters of fact—for there is usually not much dispute about the facts—than of inference, and must therefore assume different aspects according to the degree of importance with which they are invested in different minds.

Take, for example, the consideration of those properties of the metals which seem to some people to mark off these substances very clearly from the remaining elements, which are commonly referred to as non-metals. Of course any attempt to arrange natural things into groups, the members of every one of which are distinguishable sharply from the members of other groups, fails hopelessly when such attempt is carried too far; but this need not prevent such attempts from reaching that measure of partial success which is practically useful. It is, in fact, impossible to avoid classification, for no sooner does a series of facts or phenomena become known than the mind involuntarily proceeds to arrange them into groups, and the pretence on the part of a few modern chemists that *no* scientific distinction can be drawn between metals and non-metals is not likely to be permanently maintained. The want of definiteness on this point in the book before us is to be regretted. We are told (pp. 5, 6) that "although the division into metals and non-metals is thus seen to be one which does not admit of exact definition, it is none the less true that the metals as a class do possess certain generic properties which the non-metals either do not possess at all or exhibit only in a very slight degree," and it is a little surprising to find that "among these properties that of metallic lustre may be specially mentioned." What then about iodine, graphite and tellurium, which most people agree to place among non-metals?

Undoubtedly any attempt to provide a definition which shall be comprehensive enough to include not only the seven ancient metals, but such things as arsenic, antimony, titanium, as well as the true metals—sodium and the rest which have been made known in modern times—must fail; but that is not a reason for refusing to recognise in the great majority of those elements which show a disposition to form oxides of more or less pronounced basic character, certain other characters, chemical and physical, which, taken together, afford a useful criterion of the true metal, while for those elements which only imitate the metals in one character or more and fail in the rest, the term "metalloid," so long misapplied, might be appropriately retained. The true metal is malleable, with a good conducting power for heat and electricity, and forms no gaseous or vaporisable compound with hydrogen. The semi-metal or metalloid is brittle, a bad conductor, and in many cases produces a gaseous hydride.

The general adoption of Mendeléeff's scheme of classification of the elements has no doubt served to increase the difficulty felt as to the distinction of metal from non-metal; but even in the periodic table the non-metals are confined to the top right-hand corner, and display amid great physical diversity an assemblage of chemical characters which marks them off as a class.

Naturally there are elements which recall in respect to one set of relations the features of a metal, and in respect to another those of a non-metal, and these of course stand between; but to refuse to recognise these distinctions would be as inconvenient as a proposal to do without "orders" in botany because all botanists are not agreed about the diagnostic characters of every order in the vegetable world.

The authors have made a change of some importance in the sequence in which the metallic elements are taken for study in this volume. In the first edition they were grouped into families more or less entitled to be regarded as "natural"; but are now taken in the order of the periodic system. There is, however, a sort of acknowledgment of the inconvenience of this plan for the arrangement of matters for study, inasmuch as it is departed from at the very outset, sodium and not lithium being the metal first described. It must, however, be admitted that the authors have dealt with this difficult question in the liberal spirit proper to scientific men. They point out that while the arrangement of the elements in the order of their atomic weights has brought into view the remarkable relations among their properties which are formulated in the so-called "periodic law," and that this system stands upon a very firm basis of fact,

> "the system will doubtless undergo modification as our knowledge increases, for difficulties occur which cannot at present be explained. Thus elements sometimes occur in the same group between which only a limited amount of analogy can be traced and, on the other hand, elements which have a good deal in common are sometimes separated widely."

This being admitted, it is a very doubtful advantage to have adopted the system, interesting and suggestive as it is, as the order for the contents of the book. This, however, is not of serious consequence inasmuch as the volume is provided with a good index, and old-fashioned people who might be disposed to look for copper, silver and gold elsewhere will have no difficulty in finding a good and clear account of them, notwithstanding that they are sandwiched in between the metals of the alkalis and the metals of the alkaline earths.

The volume concludes with the history of those two remarkable substances argon and helium, and winds up by pointing out that "the existence of two substances having the properties of argon and helium is not in any way indicated in the periodic classification of the elements, and it is probable that their discovery will lead to modifications of that hypothesis," a statement with which even the most fanatical of periodic chemists will find it difficult to disagree.

One is tempted to think that, if we were not so familiar with it, *hydrogen* is the element upon which, in connection with any system of classification, wonder must be concentrated. Undoubtedly a positive element, similar in general chemical character to a metal, yet its volatility removes it far from any acknowledged metal, and its low atomic weight separates it in the periodic scheme from all the other gaseous elements. Its nearest allies are the metals of the alkalis, and towards them it stands, so far as physical character is concerned, much in the same relation as nitrogen to arsenic and antimony or oxygen to selenium and tellurium. And even as to chemical relations its position is analogous to that of nitrogen or of oxygen, notwithstanding that among the negative elements chemical activity generally diminishes as atomic weight increases; while in the series Li, Na, K, Rb, Cs, chemical activity increases with atomic weight.

The question of the molecular weights of the metals is one of great interest. It has been known for a long time, from the vapour densities of mercury, cadmium, and zinc, that the molecules of these metals are monatomic, while the semi-metal arsenic forms in the state of vapour a molecule composed of four atoms. Potassium and sodium are unmanageable, and no other metal is volatile enough to afford by this process any trustworthy results. But attempts have been made to estimate the molecular weights of a great many metals by observation of the depression of the freezing points of certain fusible metals—for example, of tin, lead, or bismuth (Heycock and Neville), or of the lowering of the vapour pressure of mercury (Ramsay) by solution in these fluids of determinate quantities of the metals under consideration. The general result of these experiments tends to the conclusion that in nearly all such cases the molecules are composed of one atom only. There is evidently room for further experimental inquiry in this direction, for there seems at present to be some conflict of testimony. The molecule of arsenic in the vaporous state is undoubtedly As_4, and its chief oxide is also admittedly As_4O_6. In like manner the molecule of antimonious oxide is Sb_4O_6, and by analogy one must conclude that the vapour of antimony, although not actually observable, must be tetratomic or Sb_4. When these vapours condense, either to the liquid or solid state, it would be contrary to all experience in other cases to suppose that they dissociate, and that the four atoms part company from each other. Yet this is what the results derived from freezing point or vapour pressure experiments would lead to. There is also the curious fact that the theory of Dulong and Petit, which states that specific heat in the solid elements is inversely as the *atomic* weight, points to the atom, and not any congeries of atoms, as the physical unit in the solid. So that, for example, arsenic and cadmium, so different as regards vapour density, agree in atomic heat; thus—

	Specific Heat	×	Atomic Weight	=	Atomic Heat
Arsenic	·0814 (Regnault)		74·4	=	6·05
Cadmium	·0542 (Kopp)		111·3	=	6·03

Probably in the solid the molecules settle down into some tactical relation to one another, in consequence of which the atoms of neighbouring molecules are brought as near together by cohesion as the atoms in any one molecule are by chemical attraction.

Turning again to the volume before us, there is much that must be interesting to readers of all classes, and especially in connection with the metallurgy of such metals as sodium and aluminium, concerning which Sir Henry Roscoe is in a position to give trustworthy information. As is well known, sodium was first obtained in 1807 by Sir Humphry Davy, who got it by the electrolysis of caustic soda. Subsequently Gay-Lussac and Thénard succeeded in decomposing that compound by means of metallic iron at a high temperature, but up to quite recent times it has been usual to manufacture it by distilling a mixture of dry sodium carbonate and charcoal, the metal passing over accompanied by the escaping carbonic oxide. But even in well-conducted operations the yield of metal corresponded to not more than about one-third of the theoretical amount.

A great improvement was introduced by Mr. Castner some fifteen years ago when he replaced sodium carbonate by caustic soda, and employed an intimate mixture of iron and carbon as the reducing agent. It is now interesting to learn that he has accomplished another great advance which consists in adapting the original method to manufacturing purposes, and we are told that whereas—

> "in the year 1807 Davy, with his battery of 100 cells, found it impossible to produce the effects of decomposition on pieces of soda of more than fifteen or twenty grains in weight, the process has now been so amended that the plant at the works of the Aluminium Company, Limited, at Oldbury, manufactures about five tons of sodium per week."

What becomes of so large a quantity of this strange metal, considering that the Aluminium Company no longer makes aluminium, and sodium is no longer used for this purpose anywhere, is a question which naturally arises. And the answer is supplied pretty well by the book. Sodium is used for the manufacture of cyanides, the consumption of which in the process of extracting gold from poor ores and tailings must be now enormous. It is also used for the manufacture of sodium peroxide, for the production of metallic magnesium, and in the preparation of certain complex carbon compounds, of which the most important commercially is antipyrine.

The history of the metal aluminium has also many points of interest. The discovery of the metals sodium and potassium by Davy placed in the hands of chemists new and very powerful agents, by which it became possible to isolate from their compounds several elements the existence of which was well recognised, but which had previously resisted all attempts to obtain them in a separate state. Among these was aluminium, which was seen for the first time in 1828 by Wöhler, who succeeded in decomposing the chloride by potassium. With the substitution of the cheaper sodium for potassium, and the occasional replacement of the chloride by the fluoride of aluminium, this was practically the method adopted by the experimentalist and manufacturer alike down to quite recent years. The Aluminium Company, already referred to, was formed for the purpose of working such a process with the use of sodium obtained more abundantly and cheaply than before by Castner's process. All this is now changed. So long ago as 1854 aluminium was deposited in the metallic state by the electrolysis of the fused chloride of aluminium and sodium according to the method introduced by Bunsen. It was also stated to have been obtained by the electrolysis of aqueous solutions of certain aluminium compounds, but this appears to have been a mistake. The method now adopted consists in subjecting to the electric current pure alumina in a fluid state, that is fused alone or dissolved in melted cryolite.

Now that the energy of falling water is being turned to account on a large scale, works have been established at Neuhausen near the falls of the Rhine, at Niagara, and at Foyers in Scotland, for the production of the current by means of vast dynamo machines, and its application, among other chemical manufactures, to the reduction of aluminium.

Little else remains to be said of the book except by way of commendation. A few minor matters have been passed over rather slightly. Thus the solubility of calcium sulphate in water containing chlorides is a matter of some importance from a technical point of view; and the simple statement of the text (p. 437), that "according to Anton 1 part of gypsum dissolves in 122 parts of a saturated solution of sodium chloride," is neither very precise, nor is it of much practical use. A long series of determinations of the solubility of calcium sulphate in chlorides is provided by the work of Lunge (*J. Soc. Chem. Ind.*, 4, 31), and by that of Tilden and Shenstone (*Proc. R. S.*, 38, 331). As regards the temperatures supposed to be indicated by the colours developed upon the surface of steel in the process of tempering, it has been shown, more especially by Turner, that these colours can be *successively* developed by protracted heating to the same temperature, and under any circumstances are not to be interpreted to within a considerable range of degrees. As the interesting lead tetrachloride has been properly mentioned, the more stable tetracetate (Hutchinson and Pollard) should have been noticed at the same place.

The whole of such a volume as this should be read attentively by every serious student of chemistry; and if this treatise does not displace all other English text-books devoted to mere description, it will be solely on account of the unfortunate but unavoidable high price, a consideration which necessarily influences so many students in their choice.

W. A. T.

SUBMARINE CABLE TESTING.

Student's Guide to Submarine Cable-Testing. By H. K. C. Fisher and J. C. H. Darby. Pp. 165. (London: *The Electrician* Printing and Publishing Co., 1897.)

THIS practical and useful little book is designed as its title indicates, and, as its authors state in their preface, to meet the requirements of young students in this particular branch of submarine cable engineering, and to endeavour to place before them in as concise and lucid a manner as possible, not only the practical problems involved in the study of cable-testing, but also the simple algebraical formulæ necessary for their solution.

Many of the large submarine cable companies now demand that their employés shall qualify themselves in electrical subjects, and shall pass certain examinations before being considered eligible for promotion from the lower to the higher grades of the service.

This very proper requirement on the part of the companies has resulted in stimulating their staffs to greater exertions; but it has been found that the ordinary text-books in circulation are either too theoretical and advanced for beginners, or fail to deal with and thoroughly explain just those particular points upon which they seek instruction.

The authors of the little work under review—practical electricians and cable engineers themselves—were constantly being asked for information upon these points, and their first effort to meet this demand upon their time and patience took the form of a small pamphlet entitled "Notes on Practical Cable-Testing," of which a small number was printed and issued privately.

This first effort was so far appreciated, as to encourage them to hope that a more ambitious work, carried out on the same lines, might be found still more useful; and although, as the authors modestly remark in their preface, "the scope of the present work is bounded by the requirements of the electrical examinations for supervisors, and the ordinary electrical outfit of all the company's stations," we venture to think they have so far succeeded in their purpose, that this book will be found of practical value, not only to those for whom it was originally written, but to all desirous of studying and understanding this most interesting subject.

As we have already observed, too many of the existing text-books are the works of theorists who do not concern themselves with the practical features of the matters upon which they write; in fact, who do not possess the necessary practical experience themselves, which would enable them to do so satisfactorily; and we think, therefore, that this little book will be accepted, and rightly so, as a useful contribution not only to our knowledge, but also to submarine cable bibliography.

The work is divided into two parts: the first dealing with simple testing, such as the measurements of resistances and of electrostatic capacity, together with the testing of batteries for electromotive force and interna resistance; and the second, with the various known methods which are adopted for the localisation of faults in submarine cables.

In a book of this description it would be invidious to criticise too closely, or we might be tempted to question some of the definitions of terms in the opening chapter, such as "Farad—the practical unit of capacity" and "Shunt—a conductor, usually a resistance box, for leading into another channel part of a current that is too powerful for the immediate purpose."

The idea, however, seems to have been to convey to the reader the practical sense of things, and not to split hairs as to choice of terms. The chapter on that electrical *pons asinorum*, the theory of the Wheatstone Bridge, is especially clear and well put, and the student who reads and digests it thoroughly may cease to frown at the name of Kirchhoff, the sum of whose quantities has frequently an aggravating habit to the student mind, of equalling nothing.

Paragraphs 54-55, pp. 55-59, explaining the necessity for ascertaining the proper time constants to be allowed in charging long cables, whose resistances it is required to measure, are very important to learners, and should be carefully studied. Three simple rules are given for determining these constants in the cases of (1) a perfect cable, (2) a broken cable, and (3) a faulty cable, and it is suggested that an ordinary metronome, such as is used in beating time for music, will be found of great assistance in measuring the time for charging and discharging.

Articles have recently appeared in the technical journals, and some discussion has followed, upon the relative merits of the "scale zero" as opposed to the "false zero" method, for fault localisation especially. Upon this head the authors remark: "We will now describe the 'false zero' method. We consider this method by far the best and most accurate . . . especially with a faulty cable"; and again at p. 54, with special reference to Mance's method for eliminating the resistance effect of an earth current, they observe: "It may be pointed out here that the statement that R, the resistance equivalent to the E.C. varies inversely as c, the current to line, is not quite correct in the case of faulty cables. If the testing current be reduced or increased, it slightly *reduces* or *increases* the E.M.F. due to *polarisation of the fault*, and therefore the current set up thereby, but we have not found this error to be as a rule appreciable."

The tests for the measurement of capacity are clearly explained as far as they go, and numerous references are given to various text-books and other publications, to enable the student to follow out for himself the study of the effect of the phenomenon of absorption upon different dielectrics.

In the second part of the book, a description of the various tests employed for localising partial faults, and total breaks in submarine cables, is prefaced by a few interesting preliminary remarks upon the nature of these faults, and their behaviour under the influence of the testing current.

It is interesting also, and instructive, to note the headings under which they are grouped, such as those due to submarine borers, to chemical action, *fish-bites*, punctures, &c.

We must, however, take exception to the expression "Kennelly's law" in the description of his tests for total breaks. A "law" in this sense must be absolute and unchangeable, whereas Kennelly's "*rule*" that, "when the exposed area of a break is constant, its resistance varies inversely as the square root of the current strengths passing through it" is only true between certain limits of current. Kennelly pointed this out himself, and Schaefer has since demonstrated that beyond 25, and up to 50 milli-amperes, the resistance varies inversely as the 1·3th root of the current strengths.

The authors have endeavoured to make the various sections of their book complete in themselves, and have added a number of diagrams of connections for signalling on cables, which form a new feature in works of this description, and which, with the various tables of temperature coefficients, will no doubt be found useful.

We may add that nearly all the examples are actual tests of cables, and are given very fully in the hope that they may tend to throw a practical light upon the explanations of the various tests.

In conclusion, we feel it incumbent upon us to recommend every student of submarine cable engineering to add this little volume to his library.

BRITISH MOTHS, AND THE GENUS DIANTHŒCIA.

The Lepidoptera of the British Islands. A Descriptive Account of the Families, Genera and Species indigenous to Great Britain and Ireland, their Preparatory States, Habits and Localities. By Charles G. Barrett, F.E.S. Vol. iv. Heterocera. Noctuæ. 8vo, pp. 402. (London: Reeve, 1897.)

THE fourth volume of Mr. Barrett's elaborate work includes ninety-eight species (three of which, however, are regarded by the author as doubtfully British) distributed among thirty genera of the *Noctuæ Trifidæ*, to which group belong by far the larger part of the European stout-bodied, night-flying moths. This gives us an average of something like four pages to each species, though many of the notices run to six or seven pages; and on such a scale it will require twenty volumes to complete the life-histories of our British Lepidoptera.

Mr. Barrett is well known as one of the best of our practical entomologists, and the history of every species is worked out with extreme care, the observations of numerous lepidopterists throughout the British Isles being freely utilised, in addition to those of the author himself. The foreign range of each species is also briefly indicated, though the character and extent of the book prevents almost any allusion to allied species not occurring in Britain, except so far as such notices are absolutely necessary to elucidate British species.

Considerable space is devoted to the genus *Dianthœcia*, which includes eight or nine British species, most of which are coast-frequenting insects with us, the moths being found flying over *Silene* in the evening, often on precipitous sea-cliffs, where it is not unfrequently a task of some difficulty and danger to capture them. The larvæ are described by Mr. Barrett as "smooth, plump, with the head small, usually feeding on or in the blossoms or seed-vessels of plants belonging to the *Caryophyllaceæ*."

Britain is called by the French entomologists, *le pays de variétés*; and the British species of *Dianthœcia* are extremely variable with us, especially in outlying parts of our islands, where isolation tends to encourage variation. Mr. Barrett's account of the variation of *D. conspersa*, Esper, an unusually widely-distributed species with us, is well worthy of the attention of scientific naturalists, and alone furnishes a sufficient reply to any persons who may imagine that our British Lepidoptera may be regarded as worked out. These notes are too long to reproduce in their entirety, as they extend to nearly two pages; but we may perhaps be allowed to quote a few sentences relative to the variations exhibited by *D. conspersa* in the Scottish islands, the entomology of which has only been systematically investigated within the last twenty years or so.

> "It is in the Shetland Isles that the most extraordinary forms are found—the white markings utterly suppressed, or the stigmata alone white, or yellow, or pale ochreous, or black-brown and only indicated by blacker margins; the subterminal line only indicated by its attendant black clouds, and sometimes the whole surface of the fore-wings smoky-black or olive-black, with but a faint dappling of blacker lines and crescents; on the other hand, some specimens in these islands are of the form in which the ground colour is intensified, but the markings, though curtailed, sharply white. This last form is also found in the West of Ireland, and a specimen now before me from Sligo is singularly rich in its deep dark colour and snowy blotches. Specimens from the Hebrides are extremely beautiful, the white markings variegated with yellow and greenish-yellow, or even orange-yellow. Those from Orkney are somewhat similar, or with the white markings small but clear. Although there are so many apparently local strains of variation, all are intimately connected by intermediates, so that, except in some degree in Shetland, it is impossible definitely to separate the species into varieties. . . . Mr. McArthur, who has collected very extensively in [the Shetland] Islands, assures me that the darkest suffused and nearly unicolorous forms are found mainly on the East coasts, more particularly of the island of Unst, where the rocks among which the food-plant grows are of a very dark colour; while on the West coast, where the rocks are of a paler colour, the forms found are more nearly normal, with intermediate varieties. Also that in the Hebrides, along with rocks ornamented with yellow lichens, he has found those varieties of the moth having an orange- or olive-yellow tinge. This is the more remarkable in that the moth does not appear there to sit upon the rocks, or to give up its usual habit of hiding in the daytime among herbage."

Another very interesting species of the same genus is *Dianthœcia Barrettii*, Doubleday, which was originally captured by Mr. Barrett at the Bailey Lighthouse at the Hill of Howth, near Dublin. It has scarcely been taken anywhere but on this hill, except singly at the Land's End, Ilfracombe, Tenby, Carnarvonshire, and perhaps in the south of Ireland. Mr. Barrett, in common with several other lepidopterists, now regards it as a variety of the continental *Dianthœcia luteago*, Hübner, remarking: "There is at first sight no resemblance between them, yet, with the exception of the colour, no distinction of any importance can be found." In the larva the spiracles are said to be black in *D. Barrettii*, and flesh-coloured, encircled with black in *D. luteago*.

But before the identity of the two forms can be taken as established, broods of each should be reared in different larva-cages by the same observer, and the differences between them carefully noted at each stage. It may be that *D. Barrettii* is only an incipient species at present; but it is equally probable that further observation may show that it is abundantly distinct from *D. luteago*. We incline to think that it is a little premature to class the two forms together, even tentatively, without better evidence.

We hope that Mr. Barrett will succeed in completing the great work on which he has now made such good progress, and which is likely to remain a most valuable record for all time of the state of our knowledge of the British Lepidoptera at the end of the present century. We cannot speak of the plates, as we have only the smaller edition, without illustrations, before us while writing. W. F. KIRBY.

OUR BOOK SHELF.

A Suggested Improvement of the Current Theories of the Tides. By J. H. S. Moxly. Pp. 43. (London: Rivingtons, 1898.)

IN this brochure, Mr. Moxly expresses his dissatisfaction with the theory of the tides, as ordinarily accepted, and submits an alternative explanation. Although he opposes the views generally held, he does not exhibit that spirit of antagonism and adopt the language of abuse that too frequently disfigures the writings of those who dissent from authoritative teaching. Where it has been necessary to refer to the papers of Airy or of Darwin, these names are generally mentioned with the respect due to their great reputation, and therefore, though we are as thoroughly opposed to Mr. Moxly as he is to the mathematicians just mentioned, we shall endeavour to adopt the same courtesy towards him that he has shown towards others.

The author considers that the tides are heaved up by the earth's gravity. The differential attraction of the sun and moon simply gives an opportunity for the earth's gravity to display itself in this manner. This action is illustrated by reference to a football. When the leathern covering is injured, or a seam gives way, the inner india-rubber case bulges out through the opening in the outer cover. "The pressure of the outer case had been removed from one region of the ball, and the pressure of the part which remained did the rest. This, I take it, is exactly how the pressure of the earth's gravity produces the tide." We are all prepared to admit with the author, that the tide-raising force is directly opposed to the action of the earth's gravity, though we might not adopt his phraseology. But another elementary proposition shows that the tide-raising force varies inversely as the cube of the distance of the disturbing body, and we fail to derive this from the football illustration, or from anything directly asserted in the pamphlet, though we notice that some mathematical formulæ are quoted in which the third power of the disturbing force is given. Moreover, by another illustration drawn from the observation of pressure applied to a water-bed, the author concludes that the crest of the tidal wave will always be directly under the moon. We understand this to apply to a uniformly ocean-covered earth. From this it is to be gathered that Mr. Moxly does not consider that the angular distance between the tidal crest and the moon is a function of the depth of the ocean, which in the wave theory of the tides it clearly should be.

But the test of the accuracy of a theory must at last rest in the comparison of its results with those of observation. Mr. Moxly admits this, and therefore a considerable part of the pamphlet is devoted to showing that his theory explains observed facts. Unfortunately, we are not able to follow the author very clearly in this part of his treatise; but so far as can be seen, the conclusions are inadequate. For instance, the tide at Kerguelen is triumphantly pointed to as proving the coincidence of the tidal crest with the moon's passage over the meridian; but there is no reference to Fiji, where the tide lags some six hours, and the conditions for observation appear equally favourable. We do not propose to follow the author in his discussion of such niceties as the diurnal tide, and prediction for a particular port. If any other remark be needed to indicate the character of the work, it will be found on p. 40: "the swaying of the axis of the tidal spheroid about the axis of the earth's rotation gives us a clear explanation of the production of the phenomenon of nutation."

A Practical Physiology: a Text-Book for Higher Schools. By Albert F. Blaisdell, M.D. Pp. vi + 448. (Boston, U.S.A., and London: Ginn and Co., 1897.)

THIS is not a handbook for the physiological laboratory, but a school lesson-book on elementary anatomy, physiology, hygiene, nursing, and ambulance work. A manual of this kind can hardly be otherwise than superficial, but the information it contains ought to be accurate as far as it goes. In the present case, however, signs of carelessness abound throughout; and the teaching, when not absolutely erroneous, is often misleading. A few instances will suffice to give an idea of the traps which await the unwary student of these pages. Peyer's patches are stated by implication to consist of glands which secrete intestinal fluids. In a figure representing the heart and great vessels, the innominate artery is called the "right subclavian," the left common carotid appears as the "right common carotid," and the left subclavian is labelled the "left common carotid." In a diagram intended to illustrate intestinal absorption, the veins of the mesentery are represented as inosculating with the lacteals. "The power which the pancreatic juice possesses of acting on *all* the food-stuffs appears," it is asserted, "to be due mainly to the presence of a specific element or ferment known as *trypsin*." It is impressed on the student that he should learn how to tie a "reef" knot. But in the figure given to illustrate the directions of the text (which are correct), the author has delineated an unmistakable "granny." After these specimens of erroneous and careless treatment of the subject, it is of minor importance to note that in the repeated denunciations of the use of alcohol and tobacco, inserted, as the preface informs us, in compliance with the laws of most of the States, little or no attempt is made to distinguish between the effects of ordinary and toxic doses of these substances. A book like the present is far more likely to retard than to advance the cause of elementary physiological teaching in schools. F. A. D.

Die Photographische Praxis. Part i. By Prof. H. W. Vogel. (Berlin: Gustav Schmidt, 1897.)

OUR first words must be to congratulate Prof. Vogel that he has recovered from the illness that has delayed for three years the completion of this section of the new edition of his "Handbuch der Photographie." The part now issued is the first part of the third volume, and deals with photographic studios and apparatus (excluding lenses, which are treated of in a previous volume) and the negative processes with collodion and with gelatine emulsions. The chief differences between this and the previous edition are that the practice of photography is now regarded from a general rather than from a merely "professional" point of view, portable apparatus and shutters being considered, and that chapters are given on the use of colour sensitised plates and film photography. Collodion, on account of its continued application in the reproduction processes, retains the premier position; gelatine following with about the same number of pages devoted to it. Considering the space given to the various branches of the subject, it is surprising that some of the most important advances made during the last ten years or so are not represented. We refer to advances of immediate practical importance, such as the methods of determining the exposure required, recent methods of determining the sensitiveness of plates, and the efficiency of shutters. Intensification also is dealt with in a very inadequate manner. But looking at the volume as a whole, it is a valuable addition to photographic literature, and the opinions and preferences of its distinguished author must always be of interest to English students.

The Miner's Arithmetic and Mensuration. By Henry Davies. Pp. x + 316. (London: Chapman and Hall, Ltd., 1898.)

THIS little volume comprises a collection of questions in arithmetic, the larger number of which are purely and simply arithmetical, ranging from compound addition to cube roots, whilst a smaller number illustrate the mode of solving some of the simpler numerical problems with which the miner has to deal. The work is naturally more or less elementary, and the formulæ given appear to be in most cases fairly correct; in some instances, however, as in the formulæ given under the head of "the barometer," simplicity has been gained only at the expense of accuracy.

The book seems well calculated to serve its purpose, that of enabling the miner to learn how to answer some of the easier numerical questions usually set in the mine manager's examination, without requiring from him any particular mental effort. Whether it is, however, upon the whole a good thing that the pupil, as well as his teacher, should have a collection of rule of thumb methods, that tax merely their memories, without appealing at all to their intelligence, is quite another matter.

Inspector-General Sir James Ranald Martin, C.B., F.R.S. By Surgeon-General Sir Joseph Fayrer, Bart., K.C.S.I., LL.D., &c. Pp. xvi + 203; plate i. (London: Innes and Co., 1897.)

THE name of Sir James Ranald Martin is known to few, and the details of his career to still fewer. It is for this reason that the volume before us will be welcomed by all interested in the birth and development of the medical profession, and sanitary science in India. Sir Ranald Martin left sanitary science, in the broadest sense of the term, and the position of the medical officer in India, in positions very different to those in which he found them. It would have been difficult—indeed, impossible—to have found a better biographer than Sir Joseph Fayrer, whose intimate knowledge of all that concerns medicine in India is absolutely unrivalled. So far as we are aware, the *rôle* of biographer is new to Sir Joseph; we can only say that from apparently scanty material he has constructed a biography accurate, interesting and instructive.

The biographer, put shortly, describes Sir Ranald's early life and early work in India, following him through the disastrous Burmah campaign 1824-26. Then follows a record of his public services in India. Amongst these, perhaps, the most striking are the inauguration of a system of medical statistics and the sanitary improvement of Calcutta. In 1840, at the age of forty-four, Sir James Ranald Martin returned to London, and took up his residence in Grosvenor Street. From this onwards, with the exception of some time devoted to literary work, which bore fruit in the shape of his treatise "On the influence of tropical climates on European constitutions," he devoted himself entirely to administrative work in connection with medicine and sanitary reform in India. His services in this direction met with but tardy public recognition, for it was not until 1860, sixteen years before his death, that he obtained his C.B. and knighthood. His memory has been perpetuated in that branch of the profession which he so adorned by the establishment, at Netley, of the Martin Memorial Gold Medal, which is presented to the surgeon on probation who takes the highest place in military medicine at the final competition. The biography is exceedingly pleasant reading, and the author has done well to incorporate in it letters from many interesting persons to Sir Ranald, and also some extracts from official documents, in the compilation of which he was concerned. F. W. T.

The Chemistry of the Garden: a Primer for Amateurs and Young Gardeners. By Herbert H. Cousins, M.A. Pp. xv + 141. (London: Macmillan and Co., Ltd., 1898.)

THIS little book is very clearly and pleasantly written. It contains much valuable practical information respecting garden soils, the use of artificial manures in horticulture, the preparation and application of effective fungicides and insecticides, and various other matters. The book is designed for the use of persons who have not received a scientific education, and we should think it will exactly meet their wants; there is, however, much in it that will well repay the perusal of a higher class of readers. There are a few minor points which seem open to criticism. "Pod-plants" is not a good distinctive name for the *papilionaceæ*, as the *cruciferæ* are also podded. The popular use of the word "germ," as descriptive of certain races of living beings, should surely be discouraged as fundamentally incorrect. Nor is there any advantage gained by speaking of "muriate of potash," though the term still lingers in commerce. If a person who knows nothing is to be taught, it is surely needless to burden him with archaisms which he must unlearn if his education proceeds any further. Agricultural chemists will, we think, demur to the same valuation being applied to the nitrogen of ammonia and to the nitrogen of insoluble organic manures. R. W.

The Naturalist's Directory, 1898. Pp. 125. (London: Upcott Gill, 1898.)

THE sub-title explains that this book is "for the use of students of natural history, and collectors of zoological, botanical, or geological specimens, giving the names and addresses of British and foreign naturalists, natural history agents, societies and field clubs, museums, magazines, &c." The volume is more remarkable for what it omits than for what it includes, and disappointment will be saved by not referring to it for the addresses of well-known naturalists.

The Teacher's Manual of Object-Lessons in Domestic Economy. By Vincent T. Murché. Vol. i. (Standards I. and II.) Pp. 250. (London: Macmillan and Co., 1898.)

THIS manual is, the preface informs us, "designed primarily to meet the requirements of the Education Department in the Class Subject of Domestic Economy, as laid down in the Code for 1897." It will be serviceable to the teacher in indicating what to show, do, and describe during object-lessons on materials used for food; and it contains a large amount of clearly explained and well-arranged facts about common things.

Storm and Sunshine in the Dales. By P. H. Lockwood; with a preface by H. G. Hart. Pp. 94. (London: Elliot Stock, 1898.)

A BOOK containing many personal observations on outdoor nature, expressed simply and sympathetically. The author is a fervent admirer of the natural beauties of Yorkshire dales, and his descriptions may lead others to share his enthusiasm, notwithstanding the fact that the scenes he depicts are mostly "glimpses of the obvious."

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

A Dust Shower.

PARAGRAPHS have recently appeared in several of the daily papers to the effect that a dust storm had been encountered off the west coast of Africa by the mail steamer *Roslyn Castle*, and that the dust had fallen on the deck for 900 miles. I was fortunate enough to secure a sample of this dust, which actually fell on the deck, with the following note affixed:—

"Ship covered with fine red dust off west coast of Africa. Lat. 22·5 N. Long. 17·25 W. February 15, 1898."

"Dust fog encountered with for 900 miles. February 18, 1898."

This dust is extremely fine, and consists chiefly of minute grains of quartz and flakes of brown mica, some of the former being well rounded.

I cannot find any trace of glass or other thing to suggest a volcanic origin to the dust; but it is undoubtedly a very fine sand, in all probability derived from the Sahara, although no mention is made of the direction of the wind when the dust fell.

Although cases of volcanic dust being transported for long distances are fairly frequent, those of sand appear to be less so.

Sir A. Geikie ("Text-Book of Geology," p. 337) mentions two cases of the transportation of sand from the Sahara; in the first instance it fell in the Canaries, in the second it was traced as far as Boulogne-sur-Mer. In the present case the distance of transport is probably greater than the one, and less than the other. C. ST. A. COLES.

The Solution of Quadratic Equations.

IN your issue of February 24 a review appears of "Chambers's Algebra for Schools." Your reviewer concludes with a lament of the probable uselessness of protesting against the method of solving quadratics by "completing the square."

Your reviewer might do something towards removing this "national fetish" if he would explain what method is taught elsewhere, to replace this out-of-date procedure. Before this vigorous onslaught, I feel ashamed to confess that I can recall no general elementary method, that does not depend on the completion of the square.

In my desire to free myself from a possibly antiquated "cult," I am, however, willing to undergo this humiliation, in the hopes that I and others may be brought more on a level with the times. E. CUTHBERT ATKINSON.

Rugby, March 6.

IN answer to Mr. Atkinson's letter, I will explain, as briefly as I can, what appears to me to be the proper way of discussing quadratic equations.

As soon as the pupil can easily factorise such an expression as $x^2 - 5x + 6$ into the product $(x - 2)(x - 3)$, it is not very difficult to make him see that 2 and 3 are the only values of x which make $x^2 - 5x + 6$ equal to zero; or, in other words, that the equation $x^2 - 5x + 6 = 0$ can be solved when the expression on the left hand has been factorised.

It is exceedingly important that the factorising of polynomials and the solution of equations should be treated as cognate, or rather equivalent problems. A quadratic equation should always be reduced to the form $ax^2 + bx + c = 0$: then the expression on the left-hand may be factorised by inspection, or else multiplied by such a quantity that the result can be conveniently expressed as the difference of two squares; $4a$ (that is, four times the coefficient of x^2) will always do, sometimes a smaller number. This should be illustrated by numerical examples: for instance, if the equation is $2x^2 + 3x - 7 = 0$, multiply by 8: then $16x^2 + 24x - 56 = 0$, that is $(4x + 3)^2 - 65 = 0$, and $x = \frac{1}{4}(-3 \pm \sqrt{65})$. When a boy is able to appreciate general formulæ, he may be led to see that

$$4a(ax^2 + bx + c) = (2ax + b)^2 - (b^2 - 4ac) = (2ax + b)^2 - (\sqrt{b^2 - 4ac})^2$$

and hence to use the "solution by formula" when he cannot find the roots by inspection.

Mr. Atkinson may perhaps say that this method "depends upon completing the square"; this is true in a sense, of course; but the point of view is really different from the "method of completing the square" usually found in text-books. Practically, the usual method is clumsy, and inferior to the solution by formula; and from the theoretical point of view it is objectionable, because it obscures the real nature of the problem. And I feel sure that many teachers and examiners will agree with me in saying that the educational value of the process is practically *nil*: bright boys go on to the general formula, dull ones follow the rule mechanically, and might just as well be drilled in the use of the general formula itself.

G. B. MATHEWS.

WEST INDIAN RESOURCES.[1]

AS expert adviser in botanical and agricultural questions to the recent West India Commission, Dr. Morris undertook the preparation of a lengthy report dealing with the economic resources of those Colonies, the causes of whose distress were the subject of investigation. This paper formed Appendix A of the Report of the Commissioners which was issued last autumn, and the praise bestowed on it as an interesting and valuable survey by one who was specially qualified both by general and local knowledge to undertake the task, induced the Secretary of State for the Colonies to rescue it from the oblivion which is the fate of many important papers appearing in Blue Books. Mr. Chamberlain's desire to have it published in a form more accessible and convenient for the public here and in the Colonies, has resulted in its being converted into an independent volume, and now appears as the first number of an Additional Series of the *Kew Bulletin*. For this purpose the work has been revised and enlarged, a full account of the botanical organisation of each Colony, and lists of books and papers containing further information, being added.

After all that has been dinned into our ears for a long time past about the absolute necessity for the Mother Country to assist the sugar-planters by bounties or countervailing duties, it is refreshing to find a book, every page of which contains an unbiased statement of the natural resources of these unfortunate Colonies. As Mr. Thiselton-Dyer states in a prefatory note: "Dr. Morris's residence in the West Indies, his repeated visits to them, and his intimate knowledge of their conditions, have enabled him to produce an account as accurate as it is impartial of their natural and economic resources, which is certainly more complete than anything hitherto available. Why the West Indian Colonies have failed to reach success, and in what direction the path to it lies in the future, can be readily understood by any one who will take the trouble to read these pages."

The Colonies dealt with have an area about equal to that of Great Britain and Ireland, with the population of Wales. Out of the entire area little more than 2 per cent. is now under cultivation, and only 7 per cent. of the estimated cultivable area. In fact, while about a million and a half acres are being cultivated, over twenty million acres more are suitable for bearing crops. Guiana has an extent of country equal to two Ceylons quite untouched; Trinidad has the wealth of the Straits Settlements going to waste; and the unworked soils of Jamaica could be made to produce the prosperity of at least four Colonies the size of Mauritius. As is well known, the Colonies have long depended almost wholly on the sugar trade as the staple industry, everything else being unworthy of consideration by the planters. Minerals are of comparatively trifling value, being limited practically to gold in Guiana and pitch in Trinidad. Essentially the true wealth of the colonists lies in the products and resources of the rich and fertile soil. In some of the islands it has of late years been recognised that it is as well to be prepared to cultivate more than one kind of produce; but, taken as a whole, we may regard the Colonies as given up to sugar growing, and, as Dr. Morris states:

"In most of the Colonies the situation is undoubtedly aggravated by their almost entire dependence on one industry. This is a source of grave danger in more ways than one. It is dangerous commercially, for any great depreciation of prices immediately affects the whole community. It is dangerous agriculturally, for adverse seasons or hostile tariffs may plunge at any moment the entire labouring population into great distress. Again, the growth of a single crop lends itself sooner or later to the spread of disease, and it rarely leads, owing to the neglect of other resources, to the production of the largest profit. To these may be added the narrowing effects produced on those engaged in the industry, and their inability or disinclination when a crisis comes to take up any other industry."

A dozen chapters are devoted to giving a full account of the past and present of each section of the Colonies—Guiana, Barbados, Trinidad, Tobago, Grenada, St. Lucia, St. Vincent, Dominica, Montserrat, Antigua, St. Kitts-Nevis, and Jamaica. As bearing upon the question of the mistake of relying upon a single industry, Guiana affords us some interesting facts. It is the largest and most valuable of our possessions in the neighbourhood, its capabilities of development are practically unlimited, and yet it is one of the most distressed of the Colonies. The region was ceded to us by the Dutch in 1815, it has an area of 109,000 square miles, a dozen large rivers flowing into the Atlantic, and a population of a little over a quarter of a million, or less than three persons to a square mile. The inland districts are practically uninhabited, nine-tenths of the population clinging to the coast. Under the Dutch sugar, coffee, and cotton were extensively cultivated, but with the transfer to the British Crown the planters gradually concentrated their energies more and more on one article and neglected the others. In 1829 the sugar yield was 46,026 tons, coffee 9,230,486 lb., and cotton 1,596,171 lb. By 1849 the coffee and cotton estates were rapidly disappearing, and in 1887 the returns showed 134,876 tons of sugar, while all other exports had practically ceased. It is this grasping at the most valuable prize, and utterly neglecting all opportunities in other directions, that has led to the downfall of this naturally wealthy country. "The whole activity of British Guiana during the last sixty years has been confined to the narrow strip of land along the coast. In spite of the vast extent of rich and fertile lands in the interior, with the exception of the gold industry, nothing has been done to develop them, and consequently the Colony is now in so critical a condition, owing to its entire dependence on a single industry, that its very existence as a civilised country is in jeopardy." With the knowledge that under another régime coffee and cotton were successfully grown in the district, it would be absurd to suppose, as some contend, that the soil can produce nothing else than sugar. The land devoted to sugar canes is a stiff clay, and fit for little else; but then it forms only the one-thousandth part of the total area of Guiana, and, as Dr. Morris remarks, there is nowhere such an extensive area of rich and fertile lands, with a comparatively healthy climate, and within easy reach of such good markets, as the Crown lands of this district. They can grow nearly every tropical product in demand, either in the New or the Old World.

Suggestions are made and particulars given as to increasing the resources of the country by adding profitable industries to the now seriously depressed sugar trade. More than a third of the population is composed of coolies from India, and this explains the importation of 50,000,000 lb. of rice annually; but as the conditions are favourable to the cultivation of rice on the spot, it is surprising that no steps have been taken to establish rice fields, if only for purposes of home consumption. The United States import bananas to the value of two millions sterling annually, but British Guiana makes no attempt to place any fruit on the market, although one shipping company offered to take 10,000 bunches of bananas every fortnight. Coffee, cacao, cocoa-nuts, cattle rearing, and other paying industries are recommended, and also the utilisation of the extensive forests for the production of valuable timber, guttapercha, indiarubber, &c. At present the forest lands bring in a revenue of 48,000*l*. in "acre money," nearly all of which is swallowed up in the cost of collection. Under competent management these forests could be made to contribute largely to the wealth of the Colony.

---

[1] "A Report on the Agricultural Resources and Requirements of British Guiana and the West India Islands." By D. Morris, C.M.G., M.A., D.Sc., F.L.S., Assistant Director, Royal Gardens, Kew. *Kew Bulletin of Miscellaneous Information*, Additional Series I. Pp. viii + 165, and Map. (London: Eyre and Spottiswoode, Her Majesty's Stationery Office, 1898.)

But there is evidently a stubborn determination on the part of a large proportion of the colonists in the West Indies to ridicule every proposal for the introduction of new industries, and notwithstanding the ruinous experience of recent years, they insist upon regarding sugar, and sugar only, as the sole means of salvation. Any person with an open mind who attends meetings in London at which the sugar planters or their representatives discuss West Indian affairs, cannot help being struck by the general desire to leave out of consideration questions relating to subsidiary industries. Still, in spite of this unwillingness to have other things to fall back upon, subsidiary industries are making some headway, and the out-and-out supporters of sugar growing cannot but admit that this is so. At the meeting of the Royal Colonial Institute on March 8, the lecturer stated that in the four essentially English islands of Barbados, Antigua, St. Kitts and Nevis, sugar is the sole possible staple; while in the five islands, Dominica, St. Lucia, St. Vincent, Grenada and Tobago, occupied by people differing from those in the other four in language and customs, the cultivation of sugar has given place to cacao, coffee, spices, and other products. Grenada, which sixty years ago contained 119 sugar estates, is now quite independent of sugar. Colonel Duncan has established on the island the largest and most valuable nutmeg plantation in any part of the New World. Are the misfortunes of the sugar-growing islands to be attributed to the "essentially English" character of their inhabitants?

Jamaica supplies us with a good illustration of the wisdom of selecting suitable marketable commodities for cultivation, in addition to the staple industry. As in other islands sugar was here once the one great object of cultivation, and in the year 1805 the exports were 150,352 hogsheads of sugar and over 5,000,000 gallons of rum. Even within recent years sugar, rum, and molasses formed the bulk of the trade, for in 1881-82 out of the total exports, valued at 1,178,594*l*., the sugar products amounted to 910,027*l*.; but by 1895-96, when the total exports had increased to nearly 1,900,000*l*., the sugar products had declined to little more than 360,000*l*. The serious depression in Jamaica dates back many years, and when it was hinted to the colonists that it would be well to introduce other cultural industries to assist in warding off the threatened crash, the idea was received with scorn and contempt. Thirty years ago Captain Bush, an American trader, began to encourage fruit growing, but for some years the venture made very slow progress, for by 1879 the fruit exports did not amount to 23,000*l*. It was realised, however, that the time had arrived to do something to save the island, and as there were no indications of an improved sugar trade, fruit had to come to the front, and by 1889 the exports had risen to 320,323*l*., and by 1895-96 to 536,811*l*., three-fifths of this trade being in bananas. From this it will be gathered that the fruit trade of the island is already far more valuable than that of sugar. One of the defects of the new industry is that there is not sufficient attention given to the manner in which the various fruits should be packed for the markets, an art in which our foreign competitors excel. In addition to sugar and fruit Jamaica has under cultivation coffee, cacao, allspice, ginger, fustic, &c., so that the entire failure of sugar would not now be anything like so disastrous as it would have been a quarter of a century ago.

All through this excellent and comprehensive report on a very difficult question, it is to be observed that the author does not propose anything with the object of hastening the end of the great sugar industry, but he recognises the necessity for supplementing, not supplanting, the staple trade by the introduction of a variety of cultural industries which would increase the wealth of the Colonies to an appreciable extent. In an appendix Dr. Morris propounds, at the request of the Chairman of the Commission, a scheme for the establishment of a Department of Economic Botany, and for agricultural instruction for developing the resources of the Leeward and Windward Islands and Tobago, and for affording assistance to the experimental cane cultivation to be carried on, in continuance of present efforts, in British Guiana, Barbados, and Antigua, at an estimated annual cost of 27,000*l*., a scheme which, it is hoped, will be found to be accepted by the Government when Mr. Chamberlain brings the proposal for assistance before the House of Commons shortly.

H. H.

ON THE BREEDING HABITS OF THE GREY SEAL.

THE grey seal (*Halichœrus grypus*) is to be met with on many parts of the British coasts, from Orkney and Shetland, throughout the Hebrides, on the north and west coasts of Ireland, and occasionally on the south and east, on the coast of Wales, in the Wash, more rarely in the Solent, and as far south as Jersey (*Zoologist*, 1884, p. 337); hence greater opportunities for observing it, and learning something of its habits, have occurred than has been the case with the ringed, bearded, and hooded seals. Moreover, several observers have contributed information on its breeding habits and on the condition of the young soon after birth. The following may be cited. So long ago as 1837, Mr. J. Wilson, writing on the habits of Scottish seals (*Mag. Zool. and Bot.*, i. p. 539), states that the young of the grey seal is "born above high-water mark in the end of September or beginning of October, and is at first covered with white hair, which is retained for many weeks, but shed before it takes to the water." His observations are confirmed by Edmondston, who, in his account of the seals of Shetland ("Zetland Isles," vol. ii. p. 294), remarks of the grey seal that the young are brought forth in September, October, or November. Nilsson and some other writers who have followed him have expressed the opinion that the breeding season of this species is in February; and Bell, in an attempt to explain this discrepancy ("Brit. Quad.," 2nd edition, p. 267), has suggested that the milder climate of Britain permits of pairing taking place much earlier than in Scandinavia. From the united testimony, however, of other observers, there can be no doubt that this is a mistake, and that the breeding season is in the autumn. Prof. Collett, of Christiania, who some years since contributed an excellent paper on the grey seal to the *Proceedings* of the Zoological Society (1881, pp. 380-87), states that on the Fro Islands, off Trondhjem's Fiord, Norway, to which this species resorts in the breeding season, "the greater part give birth to their young in the last week of September, most usually on the 29th or 30th, or October 1—some a few days earlier and some later, but never after the middle of October." He adds: "The seals probably begin to breed at the age of four years, or at the earliest three years, and give birth to only one young one annually. The young seal at its birth is clothed with a wool-like covering, which falls off after the lapse of a fortnight. . . . The pups pass the first three weeks of their life on land until they have shed their woolly coat, often on exactly the same spot where they have been born, and pass their time exclusively in receiving nourishment from the mother and in sleeping."

As to the length of time the woolly coat is retained, some difference of opinion has been expressed. Prof. Collett, as above stated, believes that it is shed in about a fortnight, or between a fortnight and three weeks; and he derived his information from Mr. F. Borthen, the proprietor of the Fro Islands, who furnished him on several occasions with particulars concerning the seals during their stay at this group of islands. Mr. J. Wilson, already mentioned, states, somewhat vaguely, that the woolly coat is retained for many weeks. Dr. R. Ball, who furnished so much information to William Thompson, of Belfast, for his work on the natural history of Ireland, writing of the grey seal (*Trans. Roy. Irish Acad.*, vol. viii.) has observed more precisely that the very young females are generally "of a dull yellowish white, with rather long hair *which falls off in about six weeks* after birth, and gives place to a shorter and more shining coat of a warm dingy yellow, variously blotched with blackish grey, the whole gradually becoming more dull, and a general dark shade spreading over the back as the animal advances in age."

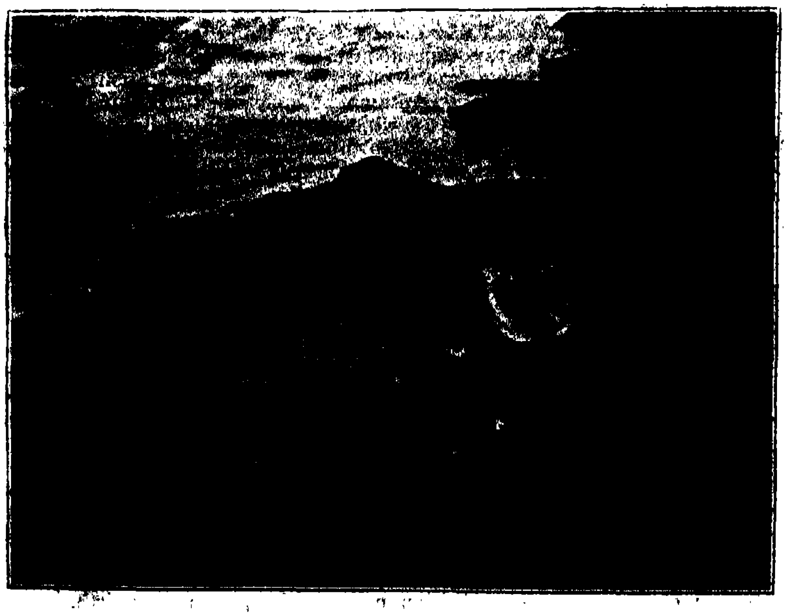

FIG. 1.—Young Grey Seal shortly after birth.

On December 24, 1881, one of the Trinity pilots, whilst off the Long Sand in the Lynn Roads, saw a large seal watching over the dead carcase of a recently born young one. On attempting to capture the old one she immediately showed fight, and had to be killed before she could be secured. This animal measured seven feet in length and five feet nine inches in girth behind the fore-flippers. It was identified as a grey seal by Mr. Thomas Southwell, of Norwich, who, in giving an account of the circumstance (*Zoologist*, 1882, p. 187), described the young one as being "of a beautiful silvery white, the muzzle sooty grey, a slight tinge of the same colour being visible on the back of the head, and for some distance along the spine."

The appearance presented by the young grey seal shortly after birth is well shown in the accompanying illustrations (Figs. 1 and 2), from photographs taken by Mr. Henry Evans, of Jura, during a visit to the Haskeir Rock in the Hebrides. Haskeir is a small rock about twelve miles west of North Uist. It is a great resort of grey seals, which breed there in October and November. It was formerly the custom with fishermen to visit this rock during the time it was frequented by the seals, and to kill them with clubs for the sake of their skins; but it is satisfactory to know, on the authority of Mr. Henry Elwes (*The Ibis*, 1869, p. 25), that this practice was put a stop to some years ago by Sir John Orde, the proprietor of the island.

From the foregoing remarks it will be evident that the suggestion (p. 346) that "the white coat is not improbably shed *in utero*," is not borne out by the testimony of the writers quoted. Nor is it only with the grey seal that this curious state of things exists. Dr. R. Brown, writing of the seals of Greenland (*Proc. Zool. Soc.*, 1868), states that the Greenland seal (or harp seal, as it is sometimes termed from the peculiar distribution of dark colour on the back) brings forth two young at a birth; that the pup "retains its white woolly coat for a fortnight or three weeks, and, *like the grey seal*, it refuses to enter the water until this is lost." Confirmation of this is to be inferred from the remark of Prof. Collett (*l.c.*), that the young grey seals during the first three weeks of their lives on land are "by no means so strictly confined to a dry place of rest, as is the case with the harp seal, which, so far as we know, never enters the water voluntarily *in its woolly coating*."

As to the common seal (*Phoca vitulina*), which pairs in September, and produces a single young one—sometimes two—in the month of June, it will not be irrelevant to refer here to the condition of the young at birth. A few years ago, towards the end of May, the late Mr. A. D. Bartlett purchased of a dealer in Liverpool four adult common seals, which were carefully transported to the Zoological Gardens. On June 9, one of them gave birth to a young one, whose appearance is thus described by Mr. Bartlett (*Zoologist*, 1881, p. 383): "It was covered with a rather thick coat of hair; its eyes very bright and wide open; it turned and rolled about, divesting itself of the outer covering of hair, which formed a complete mat upon which the young animal lay. For the first hour or two after its birth it was very active, and within three hours after its birth was swimming and diving about in the water like an adult animal. It uttered a low soft *bah*, or single call note, and looked about after its mother, and crawled towards her when she came out of the water. The mother would turn upon her side to let the young one suck. The latter was 32 inches long, and weighed 20 lbs. at its birth."

The difference between the common seal and the other species mentioned, as regards the condition of the young at birth and the shedding of the coat, is curious, and is perhaps to be accounted for in some measure by the different nature of their haunts at the time the young are born. The Greenland and grey seals bring forth their young upon rocky out-of-the-way islands, where they stand little chance of being molested, and consequently there is no need to get the young hurriedly to sea. The common seal, though breeding also on wild coasts, very often deposits the young on a sand-bank at no great distance from a fishing village, and subject sometimes to be submerged at high tides. On such banks the stay of the parent seals must be comparatively brief, for were the young not speedily able to take care of themselves, many would perish soon after birth. Thus it would seem that the greater activity of the young common seal is correlated with its conditions of life.

We have an analogous case in the difference to be found at birth in the rabbit and hare. The young rabbit born underground, where it is more or less removed from danger, is helpless and blind at birth; the young hare, deposited in a "form" on the surface, where it is more exposed to enemies, is born clothed with fur and with the eyes open. The rabbit stands in no need of early or rapid development; the young hare, on the contrary, must quickly leave the nursery and learn to shift for itself. So it may be with the seals.

J. E. HARTING.

FIG. 2.—An older pup, still retaining woolly coat.

SIR RICHARD QUAIN.

SIR RICHARD QUAIN, Bart., M.D., F.R.C.P., F.R.S., President of the General Medical Council, died on March 13, at the advanced age of eighty-one years. He had been ill for more than twelve months, and during the last half-year of his life was entirely confined to bed. His last appearance in public was when his paper on the "Cause of the First Sound of the Heart" was read before the Royal Society in June, on which occasion the President made a touching reference to the extraordinary courage which Quain displayed. His life had been one of ceaseless activity, good health, and overflowing spirits; and when overtaken by disease he appeared not to regard or understand rest, physician though he was. The paper just referred to was written in bed, and he left his bed to present and defend it. But no one was surprised at this who knew the story of the man's life.

Richard Quain was an Irishman, born at Mallow, Co. Cork, on October 30, 1816. As a child he was precocious. He was thoroughly grounded in English and the classics; distinguished himself at the public examinations, and at fifteen entered on an apprenticeship of five years as an apothecary. Even at this age he resolutely fought the cholera when it swept over Limerick. No doubt experience of this kind, and thus early, gave Quain courage and readiness in dealing with disease as a practitioner; but influences of more scientific bearing were to shape his career. The year 1837 finds him in London at University College, with a galaxy of teaching talent around him: Sharpey, Graham, Grant, Elliotson, Jones Quain the anatomist, and Richard Quain the surgeon and author of "The Arteries"—his cousins, from the same district—and as an instructor in practical surgery the great Liston, with whom Quain came to be on terms of intimate friendship. The clever young Irish lad, enjoying such advantages, immediately made his way to the front at College and University; and at the end of his curriculum as a student, obtained the coveted post of Resident Medical Officer at the Hospital.

It was shortly after this that Quain produced the brilliant research on the nature of fatty degeneration with which his name is associated for all time, and established his reputation as an original observer and thinker. Simple as the doctrine appears to us at the present day, fifty years ago it was a startling pronouncement by a young man fresh from his medical studies that fat may be, and often is, a product of the decomposition of muscular tissue, and that this change goes on in the living body. The ideas of life, nutrition, and death were greatly influenced by the doctrine. This, let us remember, was many years before Bauer and Voit, working with phosphorus in starving animals, furnished the proof experimentally and quantitatively; and Quain's claim was freely admitted by Virchow and Paget.

Although he was one of the founders of the Pathological Society, an early Secretary of it, and a frequent exhibitor at its meetings, Quain produced no other original work in this direction. His activities were being diverted into other channels. He quickly became popular as a practitioner; and having secured the valuable appointment of physician to the Brompton Hospital for Consumption, he was presently recognised as an authority on tuberculosis and diseases of the heart. Quain's personal qualities—the interest he displayed in his patients, his kindness, cheeriness, and cleverness in diagnosis and treatment—enabled him to turn to advantage his opportunities in practice; and whilst he was still comparatively young, he rose to the front rank of London consultants.

His heart was, for all this, even more closely set on the public work associated with Medicine. Medical education, medical research, medical relief at hospitals—these were the subjects at which he mainly worked, and with an energy and avidity which appeared to grow rather than wane as time passed and he attained in his old age the highest positions in the profession. A senator of the University of London; chairman of the Brown Institution, with Burdon-Sanderson, Klein, Greenfield, Horsley, and their equally distinguished successors working as professors there; one of the most prominent Fellows of the College of Physicians, which was passing through a critical period of its history; and finally President of the General Council of Medical Education and Registration, of which he had been for thirty years a member—Quain had his hands full. Yet he never appeared to grudge his time to a friend in want of advice; and he was always keen and ready for the latest information in science. He had little time for ordinary literature. His nights were spent in writing—but in writing letters. It is true that he projected and edited the great Dictionary of Medicine with which his name is associated, and he wrote a few of the articles in it; but he produced—one might say "of course"—no book of his own. He had no patience for work of such a kind. Neither was he, nor could he have been, a teacher. He was much too quick in the workings of his mind to undertake instruction in laborious fashion.

Sir Richard Quain enjoyed the priceless privilege of the close personal friendship of many of the leading men of his time—Carlyle, Landseer, John Delane, Robert Lowe, and many others, particularly men belonging to the professions and the fine arts. He was a warm-hearted, generous friend, who never spared himself when he could be of service to others, particularly young workers at the medical sciences. His position was unique—won entirely by his ability and ceaseless energy—and cannot possibly be filled by another.

NOTES.

THE International Meteorological Conference which met in Paris in 1896 appointed a permanent Committee on terrestrial magnetism and atmospheric electricity, and submitted to the Committee a number of questions for report. In order that these questions may be well discussed, it has been decided to hold an international conference on terrestrial magnetism and atmospheric electricity in connection with the forthcoming meeting of the British Association at Bristol, which will begin on September 7. Letters of invitation are being sent out by the Committee; and all foreigners who propose to attend the conference may obtain tickets of membership of the British Association, free of charge, on application to the Assistant General Secretary of the Association. Among the subjects to be discussed are: the calculation of monthly means with and without taking disturbed days into account; the publication of the monthly means of the components X, Y, Z, and the differences ΔX, ΔY, ΔZ, of the monthly means from the preceding means; the establishment of temporary observatories, especially in tropical countries; and the relative advantages of long and short magnets. The decisions of the conference upon these questions will be reported direct to the International Meteorological Conference. But though the first business of the conference will be to report upon the questions submitted to them, papers and communications on other subjects connected with terrestrial magnetism and atmospheric electricity are also invited. It is desired that such papers be sent to the Committee some time before the opening of the British Association meeting.

A NUMBER of Fellows of the Royal Society have expressed a wish that a portrait of Lord Kelvin, who served as President from 1890 to 1895, should be placed in the apartments of the Royal Society, and a Committee is now being formed to carry out this object.

A BILL to amend the law with respect to vaccination was introduced in the House of Commons on Tuesday, and was read for the first time. The Bill provides that glycerinated calf lymph, the valuable properties of which were described in NATURE a few weeks ago (p. 391), shall be placed within the reach of all, and that no parents shall be required to submit their children for vaccination by means of anything but calf lymph. Vaccination will continue, as at present, to be obligatory; but vaccination by anything but calf lymph will cease to be compulsory. At present children must be vaccinated within three months after birth, but it is proposed to extend this period to twelve months.

IN the summer of 1897 a recommendation was made to the Government of India in support of the establishment of a physical laboratory in that country for advanced scientific teaching and research. The Government of India has now reported that the initial outlay on a physical laboratory of the kind described would be 60,000 tens of rupees, and that they are unable, in the present state of the finances, to entertain the scheme.

MAGDALEN COLLEGE, Oxford, announces that a Fellowship in Medical Science will be given by the College next October. From the terms of the announcement it appears that on this occasion the Fellowship will be bestowed merely for proficiency in the sciences related to medicine, as tested by examination; but that original work in these sciences will be fully recognised as a claim to distinction. The offering of this Fellowship affords new proof of the interest which Magdalen College—that has already done so much—still takes in the advancement of natural science.

WE regret to announce that Sir Henry Bessemer, F.R.S., the distinguished metallurgist and engineer, died on Tuesday evening.

THE eighth general meeting of the German Meteorological Society will be held at Frankfort-on-Main on April 14-16.

TOWARDS the end of the year 1896, at the request of a large number of distinguished men of science, philosophy and literature, Mr. Herbert Spencer agreed to have his portrait painted by Prof. Herkomer, for presentation to one of our national collections. The portrait is now finished, and will be sent to the next exhibition of the Royal Academy. In time it is intended to offer the picture to the Trustees of the National Portrait Gallery for hanging upon their walls.

WE learn from *Science* that the New York Zoological Society has secured the 100,000 dollars needed to enable it to take possession of the site provided by the city for a Zoological Garden. The total amount subscribed is 103,550 dollars, which included thirteen subscriptions of 5000 dollars each. According to the terms of the agreement between the Society and the city, as effected last year with the Commissioners of the Sinking Fund, the Society is under obligation to raise 250,000 dollars for buildings and collections, of which sum 100,000 dollars must be in the Society's treasury on or before the 24th of this month, and it was agreed that the Society could not take possession of the site until that amount had been provided.

AN Executive Committee of the Royal Zoological Society, Dublin, has made an appeal for subscriptions towards the erection of a "Haughton Memorial Building" in the gardens of the Society, in recognition of the important services rendered to the Society by the late Rev. Dr. Haughton, F.R.S., who for twenty-one years acted as its honorary secretary, and discharged the duties of president for five years. The form which the building will take has not yet been decided, but the Council of the Society propose that it should be one with a useful purpose. Subscriptions in support of this scheme for perpetuating Dr. Haughton's memory may be sent to Prof. D. J. Cunningham, Hon. Secretary, Royal Zoological Society, Dublin.

The death is announced of Prof. Kirk, Fellow of the Linnean Society. Prof. Kirk (says the *Times*), who was of Scotch extraction, spent the greater part of a long life in the Colony of New Zealand. In connection with the Department of Woods and Forests he rendered valuable official service. He was a distinguished botanist, and his "Forest Flora of New Zealand" is the standard work upon the forest growths native to the islands. Since the production of his principal work he has continued, from time to time, to publish interesting monographs upon New Zealand timbers. A very valuable report on the trees suitable for forest cultivation in the Colony was issued by him in 1886, at which time he held the position of Conservator of State Forests in New Zealand; and he is understood to have been engaged up to the moment of his death upon a great work devoted to the botany of Australasia. Prof. Kirk was an eminent member of the New Zealand Institute, and his loss will be much deplored in scientific circles, both in England and Australasia.

We regret to announce that Dr. Ferdinand Hurter, who had been in weak health for some time past, died suddenly at his residence near Liverpool last Saturday. Dr. Hurter was a native of Schaffhausen, in Switzerland, where he was born in 1844. He early turned his attention to chemistry and its practical applications, and after serving an apprenticeship to a dyer in Winterhun, he pursued the same science at Zürich Polytechnic, whence he proceeded to Heidelberg, where he took his Doctor's degree in 1866. In the following year he came to reside in England, and was appointed consulting chemist to Messrs. Gaskell and Deacon at Widnes. On the formation of the United Alkali Company, he occupied the same position of principal chemist to that firm. In addition to much work connected with his own profession, he will also be remembered for his investigations of photometric subjects, and particularly for a very thorough inquiry, which he made some years back in cooperation with Mr. Driffield, into the action of light on the photographic film. Some of the scientific results to which he was led in the cause of the inquiry have been questioned; but his work had great effect in improving the artistic character of photographic reproduction, by his discussion of the effects of varying the exposure, and his insistence on the truthful rendering of tone. Dr. Hurter was prominently connected with the local scientific societies, having occupied the position of President of both the Chemical and Physical Societies of Liverpool.

The first number of the new volume of the *Rendiconti del Reale Istituto Lombardo* contains the conditions and particulars of the prizes offered for competition in 1898 and 1899. Most of these prizes are open to all nations; but the essays must be written in Italian, French, or Latin, and forwarded under a motto to the Secretary of the Istituto Lombardo, Palazzo di Brera, Milan. The prizes of general interest are the following: (1) The Institute's prize of 1200 lire for the most complete catalogue of extraordinary meteorological events from the most ancient times down to 1800, excluding auroras and earthquakes, which have already been catalogued. Last date, May 1, 1899. (2) The Cagnola prize of 2500 lire and a gold medal (value 500 lire) for a critical review of the theory of electric dissociation, with new experiments. Last date, April 30, 1898. (3) The Brambilla prize of 4000 lire to whoever shall have introduced into Lombardy the most useful new machinery or industrial process. Names to be sent in by April 30, 1898. (4) The Secco-Comneno prize of 864 lire for the best description of the Italian phosphate beds, and proposals concerning their exploitation. Last date, April 30, 1902. All essays must be accompanied by an envelope bearing the motto outside, and the name and address of the competitor inside.

A very valuable volume on the sanitary circumstances and administration of 220 urban districts of England and Wales has been issued as a supplement to the report of the medical officer in the twenty-fourth annual report of the Local Government Board (1894–95). The volume summarises the results of the general sanitary survey of urban districts organised by the late Dr. F. W. Barry, and carried out under his supervision during the period 1893–95. It contains the results of one of the most important pieces of administrative work ever undertaken by the Medical Department of the Local Government Board, and as a trustworthy statement of the sanitary conditions of urban districts is invaluable. The districts are arranged in alphabetical order, and under each is described the conditions of dwellings and their surroundings, water supply, sewerage and drainage, methods of excrement and refuse disposal and removal, and conditions and nature of supervision over registered premises and trades. The general character and efficiency of the administration of the sanitary authority of each district is described under a separate heading. The present report, with the one previously published on port and riparial districts, contains the results of the sanitary survey of 396 districts, the topographical positions of which are shown upon a map. It is to be regretted that a survey of such distinct value to public health could not be made to embrace the whole of England and Wales.

A practical demonstration of Dr. Carl Linde's method of producing extreme cold and liquefying air was given in the rooms of the Society of Arts on Monday and Tuesday; and the apparatus employed is described by Prof. J. A. Ewing in the current number of the Society's *Journal* (March 11). The method, it may be remembered, is a regenerative one; that is to say, the cold produced by the treatment of one portion of air is communicated to the portion which is next coming on to be treated, with the result that the air undergoes continuous cooling, which is only limited by the leakage of heat into the apparatus from outside. In Dr. Linde's apparatus the step-down or drop in temperature is produced by letting compressed air escape through a small orifice from a region of high pressure to one of low pressure. As air is not a perfect gas, in the thermodynamic sense, it is slightly cooled by the expansion it undergoes, even though it does no work. The fall of temperature is little more than a quarter of a degree for each atmosphere of difference in pressure between the two sides of the orifice; but Dr. Linde has shown that this small amount is enough to furnish the step-down necessary in a regenerative process. The gas, cooled slightly by passing through the orifice, gives up its cold to gas which is approaching the orifice. The passage through the orifice cools that gas further, and so on, with the result that a cumulative cooling proceeds. A temperature of − 200° C., or lower, may thus be obtained without much difficulty. The machine exhibited at the Society of Arts circulated about 15 cubic metres per hour in a circuit in which the fall of pressure was from 200 atmospheres to 16 atmospheres. About 0·9 litres of liquid air was produced per hour, with a continuous expenditure of three horse-power. Dr. Linde is constructing a machine of 120 horse-power for the Rhenania Chemical Works at Aix-la-Chapelle, which is to be applied to the improvement of the Deacon process of chlorine manufacture. This machine is expected to produce 50 litres of liquid air per hour.

Attention has recently been called, in two communications, to sources of error likely to arise in temperature determinations by means of thermometer readings. One of these has reference to the possibility of minute errors arising from expansion of the attached scale, when that form of thermometer is used. Opportunity for the determination of the amount of this error has offered itself at the Physikalisch-Technischen Reichsanstalt. Two pairs of thermometers, each pair being made of similar glass, and one pair divided on the stem, and the other on the scale, have been rigorously tested. The result is that the third place of decimals is not trustworthy if precautions have not been taken to remove the effects of the expansion of the scale. The other has reference to the accuracy of thermometric readings when the instrument is exposed in a medium whose temperature is rapidly changing. Dr. Hergesell, of Strassburg, in his investigation of the temperature of the air at considerable elevations, as derived from heat-registering apparatus carried in balloons, has been led to the conclusion that in order to ascertain the temperature of the air, it is necessary to take into account two corrections which can have a very important effect upon the result. One of these corrections, depending upon the velocity with which the registering apparatus is carried through the air, he has endeavoured to determine by actual experiment made in the Seewarte at Hamburg. The thermograph was mounted upon the whirling apparatus used for testing the anemometers, and driven with various degrees of velocity varying from zero to seven metres per second. The thermograph was warmed to about 30° C., and precautions taken to ensure uniformity in the distribution of the temperature. The arms were then rotated, and when the temperature of the thermograph had fallen to that of the testing-room, the resulting curves show the rate of cooling under the varying velocities.

THE second correction, which Dr. Hergesell calls the "inertia coefficient" in the paper referred to above, depending upon the variation of density of the surrounding medium, cannot be determined experimentally with the same ease. The author prefers to use the temperature recorded on the thermogram at equal, but considerable, altitudes on the ascending and descending journey. At an altitude above 4000 m. it may be assumed that the daily variation of temperature ceases, and therefore the difference of time at which the two readings are taken is immaterial. Dr. Hergesell makes use of the record of the balloon journey made February 18, 1897, from Paris. The temperature records in ascending and descending are arranged as functions of the atmospheric pressure, and show on the whole a tendency to regular deviation from each other. The greatest separation occurs at a pressure of 400 to 500 mm., while at 200 mm. the curves tend to become parallel. Dr. Hergesell assigns to the "inertia coefficient," which at the usual atmospheric pressure is unity, a value four times as great in a density corresponding to a pressure of 500 mm. In thermographs as at present arranged, the difference arising from these two sources of error, between the reading indicated and the true temperature, may amount to as much as 12°.

THE eleventh annual report of the Liverpool Marine Biology Committee has lately appeared, containing an account of the work done at the biological station at Port Erin during 1897. The year has been comparatively uneventful, but among the recent developments of the work of the station we notice a scheme for the simultaneous observation and record of surface organisms at different stations in the Irish Sea. Attention may be called to an obvious error on p. 13, in regard to the specific gravity of the sea-water in the tanks.

MR. H. L. CLARK has described the development of a viviparous Synapta which is abundant among algæ attached to mangrove roots in the West Indies. His observations induce him to support Ludwig's views concerning the degraded rank of the Synaptidæ in opposition to Semon's interpretations. In regard to the ancestry of Echinoderms as a whole, he again opposes Semon, and finds himself in close agreement with Bury; but, as the development of *Synapta vivipara* is direct and without metamorphosis, it is obvious that his criticisms of Semon's work cannot be regarded as final.

A RECENT number of the *Journal of the Society of Arts* contains an excellent review of the late outbreaks of plague in Bombay, by Mr. H. M. Birdwood. An account is given of the organised endeavours of the Government to combat the scourge, and some real idea of its extent may be gathered from the statement that up to the end of last year 56,000 deaths from plague had been reported for the whole Presidency, but that the actual number was probably not less than 70,000. Opinion appears to be unanimous that the utter disregard of the poorer natives for the commonest sanitary laws, and the horrible houses and "chawls" in which they principally live, are largely responsible factors for the firm hold which the disease has taken in the city of Bombay. The eminent authority, Dr. Cleghorn, who was deputed by the Government of India to study the position of affairs in Bombay, has vividly described the housing of the native population there. He tells us that the so-called chawls are mostly great buildings five to seven stories high on the flat principle, each flat containing a long corridor with rooms about 8 feet by 12 feet in size opening into it on either side; these rooms were usually inhabited by six to eight or even more persons, and the state of filth in these corridors, which are practically the receptacle for refuse from all the rooms, is indescribable. Each chawl contains from 500 to 1000 persons, and 70 per cent. of the native population are housed in this way. Dr. Cleghorn further goes on to say that such places were only to be seen in Bombay, and the marvel is not that so much plague abounded, but that it had not carried away at least half of the population. To cope with this terrible legacy of past generations of responsible authorities is no light task, but the Government are devoting their most earnest attention to carrying out a large and important scheme for the sanitary renovation of Bombay. It is discouraging in the highest degree to find that, despite all the heroic efforts which have been made to cope with the scourge, it has appeared with renewed strength, and an epidemic has been established for a second season in Bombay.

WE have received from the Director, Mr. N. A. F. Moos, the Report of the Bombay Magnetic and Meteorological Observatory for the year 1896. In addition to the general tables giving the readings of the self-recording magnetic and meteorological instruments, the report contains an account of the absolute measurements made during the year in order to standardise the self-recording instruments. In an appendix a short account is given of the disturbances produced on some of the self-recording instruments by the earthquake on June 12, 1897. Enlarged copies of the photographic trace of the disturbed instruments are included, which add considerably to the interest of the report. From the character of the disturbances the Director concludes that the disturbance of the magnetic instruments was not entirely of a mechanical nature, but that the earthquake did really produce a disturbance of the magnetic elements. The appendix also contains a discussion of fifty years' observations of declination made with one of Grubb's declinometers at the observatory.

THE United States Weather Bureau has published a discussion of the Floods of the Mississippi River, prepared by Mr. Park Morrill, the Forecast Official in charge of River and Flood Service. The paper refers to the chief characteristics of that river and of the basin that is drained by it, and contains valuable and trustworthy information as to the rainfall (which is the principal cause of the floods) and drainage under normal conditions, by means of a large number of tables and charts. These show that the difference in the amount of summer and winter rainfall is very great, the former being five or six times the latter in some districts. The floods occurring during the last twenty-six years, during which time trustworthy gauge readings are available, have been specially investigated; this period embraces six notable flood-years. The downfall of water in each of these has been computed, and the results are given in tabular form; the most destructive floods occurred in 1882, 1890 and 1897. In the latter year the river rose higher than was ever known below Cairo, but the duration of high water was exceeded in 1882 and 1884. One of the duties of the Weather Bureau is to issue warnings of impending floods, and it is satisfactory to note that ample notice is usually given. Indeed, so completely was the public warned on this last occasion that the Bureau was criticised for needlessly alarming the people in the threatened districts, but subsequent events fully justified its action.

FOLLOWING a recent example, the Royal Geographical Society has issued the first number of a "Year-Book and Record," designed to afford information respecting the constitution and working of the Society, and its annual progress. It seems somewhat strange that so useful a publication should not long ago have come into vogue; but we gladly welcome the new-comer as tending very considerably to enhance an interest in geography. Following the charter and bye-laws, an interesting account is given of the library and its contents, as well as of the map-room. Her Majesty's Government give 500*l.* per annum to the latter on condition that the public have access to the maps and charts. The illustrations are a pleasing feature, and give point and variety to the subject-matter. They comprise a view of the Society's house in Burlington Gardens, and selected parts of the interior, together with sundry plans; while very satisfactory reproductions are given of the two Royal medals and of the special medals which have been awarded from time to time for eminent services to geography. Some indication of size might well have been given here; if we mistake not, the gold Stanley medal was of quite heroic proportions—far larger than the illustration would make it appear. The list of recipients, beginning with Richard Lander, who received a Royal medal in 1832 for his discovery of the course of the River Niger, and the accompanying statement of the grounds of each award, is of distinct interest in this publication, connecting as it does the geographical progress of the past with the present. A long catalogue of pictures and busts is given. In another issue it would be useful, for reference, to supply painters' and sculptors' names.

HERR F. E. SUESS communicates to the *Verhandlungen* of the Austrian Geological Department some details of the earthquake at Graslitz between October 25 and November 7 of last year. It appears that the disturbance belonged to the group called "Vogtland-Erzgebirge" by Credner, and it is remarkable that at the end of the Graslitz earthquake the centre of disturbance seems to have moved to another locality as yet undetermined.

WE have received a paper by Prof. Dr. Eduard Richter, of Graz, containing an account of soundings and temperature observations made by the author in the lakes of Carinthia, Carniola, and Southern Tirol. The data discussed form the basis of the second part of the Atlas of the Austrian Lakes, produced under the joint editorship of the author and Prof. Penck, and published in the Vienna *Geographische Abhandlungen*.

THE *National Geographic Magazine* for January contains an article by Mr. Robert Stein, of the U.S. Geological Survey, on "Three Weeks in Hubbard Bay, West Greenland": the author, anxious to gain experience in Arctic work, was landed by Peary in his last expedition. Another paper, by Mr. W. J. McGee, deals with the "Modern Mississippi Problem," defined as being "not that of navigation, not even that of normal regimen as a great river, but that of the floods to which the stream is subject."

"THE Mechanics of Soil Moisture" forms the subject of a paper by Mr. Lyman J. Briggs, published by the United States Department of Agriculture. In it the author explains in simple terms such of the physical properties of liquids, including surface tension and viscosity, as are necessary to explain the retention and motion of water in the soil. To scientific students of agriculture, such an insight into the elementary laws of capillary phenomena will be useful in enabling them to explain the why and wherefore of the differences between heavy and light soils.

IN a *brochure* of six pages, on "Æther, its Nature and Place in the Universe," by Dr. Hugh Woods, published by the *Medical Magazine* Publishing Company, the author, after propounding his views on the existence of the ether and the why and wherefore of certain laws of nature, concludes by remarking: "The theory opens up far too wide a field for one man to traverse, however cursorily, especially when he can devote only a few leisure minutes to the difficult and laborious task." With this opinion we are certain that all who have read the paper will unanimously concur.

THE "Electrical Trades' Directory and Handbook," noticed in last week's NATURE, contains 1174 + clix pages in all, including the pages of advertisements. The extensive character of the electrical and allied industries may be gauged by the great size of the new volume of this Directory.

AN English edition of the two volumes of "Audubon and his Journals," the American edition of which was reviewed in NATURE of February 24 (pp. 386–7), has just been published by Mr. John C. Nimmo. Every field club and naturalists' society should add the volumes to their libraries, for they are full of interesting notes on outdoor natural history, and on the character and methods of a naturalist whose name is familiar to all observers of nature.

A SECOND edition of Prof. Heinrich Weber's systematic treatise on algebra, the "Lehrbuch der Algebra" (Brunswick: Vieweg und Sohn) is in course of publication, and the first volume of the new edition has just appeared. The scope and value of this masterly work has already been indicated in NATURE (vol. lv. pp. 25 and 481, November 12, and March 25, 1896). In the new edition the plan and method of the original work has been retained. About fifty pages of new matter have been added; corrections have been made where necessary, and paragraphs which appeared slightly obscure have been elucidated, while the section on the theory of elimination has been considerably enlarged.

AN ingenious actinograph, devised by Dr. Hurter and Mr. V. C. Driffield, has been sent to us by Messrs. Marion and Co. By means of a small double slide-rule, and a sliding set of curves movable at right angles to the motions of the rules, the variables concerned in photographic exposure are shown in their varying relations to one another. To find the time of exposure, the scales corresponding to the light, the lens, and the speed of the plate are set in their proper positions, and then the correct exposure can be read off. For photography under various conditions, such as views, portraiture, interiors, and copying, a table of factors are given. By using the actinograph intelligently a photographer may be confident of obtaining a good negative.

APPARATUS for simple experiments in physics, such as are described in manuals and text-books used in elementary physical laboratories, now take a prominent place in the catalogues o scientific instrument makers. A catalogue just received from Messrs. W. and J. George, Ltd., the successors to the late firm of Becker and Co., contains illustrations and prices of apparatus described in the volumes on practical physics by Schuster and Lee, Stewart and Gee, Watson, and Glazebrook. Similar catalogues have lately been published by Messrs. Griffin and Sons and Messrs. Philip Harris and Co. It is satisfactory to know that scientific instrument makers are beginning to understand the necessity of producing simple apparatus at a low price, now that students of physical science are expected to gain their knowledge by individual experience, even in the most elementary stages of the subject. What some of them have yet to learn, however, is that the apparatus is not intended as toys, but as a means of obtaining quantitative results; and unless this end is attainable, the instruments are of little value.

THE annual report for 1896-97 of the Director of the Field Columbian Museum, Chicago, is of interest to curators of museums, and records much progress. It is profusely illustrated by photographs of the rooms, and case-objects. In the division of economic botany, what is called a monographic installation of material exemplifying the North American forest trees is being pursued. The elements of the series comprise a branch, flowers, and fruit from the same tree, a photograph of the tree in summer, and in winter, a seven-foot length of trunk, and transverse section, a two-foot map, coloured to show the distribution of the species, and ornamental cabinet specimens. In the department of zoology the cases have been painted black inside. The report on the expedition and field work is of unusual interest. An account is given of the party which entered Somaliland under Mr. Elliot. He regards the collections made as very valuable, and probably the most important, especially as regards quadrupeds, ever brought out of any country by an expedition. Casts of heads and parts of bodies showing the muscles of the large animals were made, which will prove of the utmost service during mounting. Besides these, over 300 photographic negatives are in hand illustrating the scenery, the people, and also the animals, both living and dead. The last-named will be used in conjunction with the casts. It may be noted that the museum mostly does its own printing.

THE additions to the Zoological Society's Gardens during the past week include two Prairie Marmots (*Cynomys ludovicianus*) from North America, presented by Mr. J. Maurice Glyn; a Spotted Ichneumon (*Herpestes auropunctatus*) from Nepal, presented by the Rev. Sidney Vatcher; a Great Eagle Owl (*Bubo maximus*), European, presented by Captain Betram Goff; two Indian Chevrotaints (*Tragulus meminna*, ♂ ♂) from India, a Mantell's Apteryx (*Apteryx mantelli*), an Owen's Apteryx (*Apteryx oweni*) from New Zealand, two Cardinal Grosbeaks (*Cardinalis virginianus*) from North America, eight Undulated Grass Parrakeets (*Melopsittacus undulatus*) from Australia, a Brown Gannet (*Sula leucogastra*) from South America, a Black Lark (*Melanocorypha yeltoniensis*, ♂) from Siberia, four Chinese Quails (*Coturnix chinensis*) from China, a Black Woodpecker (*Picus martius*), a Solitary Thrush (*Monticola cyanus*), European, purchased; a Leopard (*Felis pardus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

CONSTANT OF ABERRATION.—Prof. C. L. Doolittle, from observations made at the Flower Observatory of the University of Pennsylvania, contributes a paper on this subject to the *Astr. Jour.* 428. He states "that in view of the present interest in the values of the astronomical constants, the investigation is published earlier than was intended. The result is preliminary in the sense that it is derived from a limited amount of material, which will ultimately be combined with other data." Küstner's method was employed, and he obtains a result of 20″·572 ± 0″·009, which is even larger than his recent deduction of 20″·55 from his South Bethlehem observation.

Since the adoption, then, of 20″·47 at the Paris Conference, the four most recent deductions all give higher values, viz. 20″·55 (Doolittle), 20″·533 (Fergola), 20″·57 (Finlay), and 20·572 (Doolittle).

WINNECKE'S COMET (*a* 1898).—This comet will make its perihelion passage in a few days—March 20. In *Astr. Nach.*, No. 3480, Dr. Hillebrand publishes a continuation of the ephemeris, which shows that the comet is on the borders of Aquarius and Capricornus, having passed between α and β Capricorni some few days ago. It is moving slowly in an easterly direction, but is badly placed for observation; so that it is unlikely to be seen again in ordinary telescopes until its next return in 1904.

NEW VARIABLE STARS.—We learn from the *Astronomical Journal*, No. 428, that the variability of the star S.D.M. −20°·2007, announced by Mr. Perry in No. 398 of that *Journal*, has been confirmed by Mr. Parkhurst, and in consequence the definite notation 2689 Z Puppis has been assigned to it.

The star in Gemini, announced as variable by Mr. Anderson in *Astr. Nach.* 3463, has also been confirmed by Mr. Parkhurst, and accordingly it has been called 2404 X Geminorum.

ASTRONOMICAL SERIALS.—The *Berliner Astronomisches Jahrbuch* for 1900 has recently been issued, under the editorship, as before, of Prof. Bauschinger, Director of the Rechen-Institut at Berlin. It contains particulars of the solar eclipse which will occur on May 28 of that year, and will be visible as total in the States of Georgia and South Carolina. Leaving North America the shadow band crosses the Atlantic, and strikes Europe on the coast of Portugal near Oporto, passing over Spain and Algeria.

The *Jahrbuch* contains the elements of all the small planets up to No. 425, which was discovered December 28, 1896, by M. Charlois; also opposition elements of a selected number.

The data and arrangement are the same generally as in previous years, but some important changes are contemplated in the planetary table for future years.

In the *Bulletin de la Société Astronomique* for this month there are several reproductions of the partial eclipse of the moon which took place on January 7. The photographs illustrating the various phases were taken by MM. Quénisset and Touchet; one at maximum is from a negative taken by M. Rudaux.

In the same *Journal* there is a summary of Prof. Schiaparelli's fifth "Memoir on Mars," containing his observations made during the opposition in 1886. The author has not given a general chart of the planet for this year, but his observations of 1886 happily complete our aerographical knowledge, by a rigorous examination of the north-polar region. A fine chart illustrating this region accompanies the paper, together with various aspects of the planet on different dates.

Five instantaneous photographs of Jupiter are also reproduced from photographs taken by Prof. Barnard at the Lick Observatory with the 36-inch telescope.

THE SPITSBERGEN GLACIERS.

ON Monday last Sir W. Martin Conway delivered a lecture before the Royal Geographical Society, in which he described the principal results of his second expedition to Spitsbergen, undertaken in conjunction with Mr. E. J. Garwood, in July and August 1897. It will be remembered that in the previous summer Sir Martin Conway, with several companions, for the first time explored, with any thoroughness, certain parts of the interior of the main island of Spitsbergen, throwing much new light on the physical features of the island and their mode of origin. In that year the principal attention was directed to the country south of Ice Fiord, between it and Bell Sound, the result being to show that this region was by no means the ice-clad country it had previously been considered. The principal object of last year's expedition was to examine a new section of the interior, north of Ice Fiord, which was still believed by some to be covered with an ice-sheet similar to that found in Greenland. Two districts in particular were chosen as the field of operations, the one (named by the lecturer Garwood Land) occupying the area between the extremities of Wijde Bay and Ice Fiord in the west and the sea in the east; the other lying west of the line joining the heads of Wijde Bay and Ice Fiord. For this second region Sir Martin Conway has revived the old English whalers' name for Spitsbergen as a whole—King James Land.

Although the routes naturally did not extend over a very large area, considering the comparatively short time available for the exploration, Sir Martin Conway had a most interesting story to tell of a fight against difficulties, such as are presented to the explorer by few, even of the most remote regions of the world. His graphic descriptions, reinforced by the unusually fine representations of scenery supplied by Mr. Garwood's photographs, brought home to his hearers the chief characteristics of the country in a way which could only be surpassed by an actual visit to the scenes described. He also gave the meeting an instructive study of the problems in physical geography which he thinks may be solved by his examination of the country. Garwood Land was first visited, a landing being effected at the foot of the Nordenskiöld Glacier, near the head of Klaas Billen Bay, one of the principal branches of Ice Fiord. The route led a little east of north, progress being difficult at first on account of the labyrinth of crevasses which intersect the glacier, and afterwards by reason of dense fog, and violent snowstorms. Particularly forcible was the lecturer's description of the white curtain of fog in which he and his companions were enwrapped for days together, and which in time caused a dazed feeling as if they had taken entire leave of the solid earth, and were floating in some unsubstantial nebula. The steep snow slopes entailed arduous labour in dragging the sledges, but after the fourth camp had been left some high snow domes were reached, from the summits of which views down broad valleys to the east and north were obtained, displaying a succession of plateau-fronts or bluffs of rock with *névé* both below and above them. The scenery, as seen by the evening light, was described as superb, the panorama being a glorious mass of colour. Returning to the coast, the travellers next proceeded to King's Bay on the west coast of the island in 79° N., and thence penetrated inland into an interesting region of peaks and glaciers, several of the former being climbed. The principal mountain group is known as the Crowns, and lies between the two main branches of the King's Glacier. The peaks of this region present striking characteristics, well shown by the photographs displayed on the screen. The weather during this expedition was the most perfect imaginable. A week at Horn Sound, near the south end of the island, during which Mount Hedgehog, one of the highest peaks of the Hornsunds Tinder, was climbed, concluded the expedition. Dense fog was again encountered here, and the difficulties of the ascent were altogether out of proportion to the comparatively small elevation above sea-level, the extent of the actual climb (in the Alpinist's sense of the word) far exceeding that in the case of many of the more difficult summits of the Alps.

The principal geographical result of his second visit to Spitsbergen is, Sir Martin Conway considers, the discovery that neither of the districts visited, nor, in fact, any large part of the islands except New Friesland and North-East Land, is covered by an ice-sheet. As long as a flowing body of ice is contained within definite mountain ranges, it is a *glacier*, and the districts visited were both merely glacial and mountain areas. The importance of distinguishing clearly between the two types of ice-bearing country was strongly insisted upon by the lecturer, on account of the different natural processes to be seen at work in the two. The insignificance of the excavating action of ice was stated, perhaps, somewhat too uncompromisingly; but at any rate, as was shown by Sir Martin Conway, the forces acting on the land-surface beneath an ice-sheet are mainly conservative; while in a glacial region, the rock-faces which rise above the general surface are exposed to rapid denudation, and great developments of surface-form are going forward. The "eating-back" process, recognised as a powerful agent of denudation in the case of rivers, was held to be equally effective in that of glaciers, although, of course, the result is due to aerial denudation, not to glacial erosion. The work of the glacier is to carry away the débris, the accumulation of which would otherwise arrest the process of denudation. Examples were given by the lecturer from the Bernese Oberland and the Karakoram Himalayas, in which the present surface features are, in his opinion, due to this eating-back process, which has entirely modified the original longitudinal drainage of the mountain masses. The great bluffs of the Oberland—the Eiger, Mettenberg, and Wetterhorn—show a striking resemblance to those of Spitsbergen's Sassendal.

At the close of the lecture Mr. E. J. Garwood gave some interesting details regarding the geological features of the country traversed, adding besides some graphic descriptions of the marvellous effects of colour, which give to the scenery of Spitsbergen such a unique character. Among the points touched upon was the presence in Spitzbergen, contrary to the formerly accepted idea, of a snow-line some 1200-1500 feet above sea level. The contrast in the surface features above and below this line is most marked, the lower slopes showing as well-marked a denudation curve, with gullies due to flowing water, as may be seen in our own islands, while the upper regions show the abrupt rock-faces due to frost denudation. In the case of the Crowns this has acted along the vertical joint-planes of the carboniferous limestone rocks which form, as it were, a golden crown above the purple Devonian shales of which the more gradual, lower slopes are composed. Mr. Garwood also gave an account of the en-glacial streams, which often flow in a direction at right angles to that of the main valley, and which, on the retreat of the glacier might leave behind deposits similar to the kames and eskers which have so puzzled geologists in other countries. The remarkable ice-tunnels observed may be due, he thinks, to the arching up of ice-bridges over crevasses, when these are closed up by the movement of the glacier.

A short discussion followed, devoted chiefly to the theory propounded by the lecturer with regard to the action of glaciers in modifying the surface features of a country.

Prof. Bonney, while allowing that the action supposed undoubtedly makes itself felt in certain cases, doubted the admissibility of a comparison between a plateau region like Spitsbergen and a region of narrow ridges like the Alps. The V-shaped Alpine valleys as a rule follow the lines of dip and strike, just as they do in unglaciated regions, while everywhere evidences of pre-glacial structure are to be found. From what we know of the climate of the Alps before the glacial epoch, we may conclude that in more remote times practically no glaciers existed. The characteristics noted by Sir M. Conway are, he considered, rather to be accounted for by the two distinct disturbances which have operated in the Bernese Oberland. The phenomenon adduced is, therefore, probably not more than a secondary cause in the moulding of the features of a country.

Mr. J. E. Marr doubted whether the side-glacier, shown in Sir M. Conway's diagram as hanging like a tear-drop on the mountain side, could be properly described as cutting back through the mountain wall behind it. It was important to keep clearly in view that the wearing-back process, even in the case of glaciers, was really due to the action of the weather at their head.

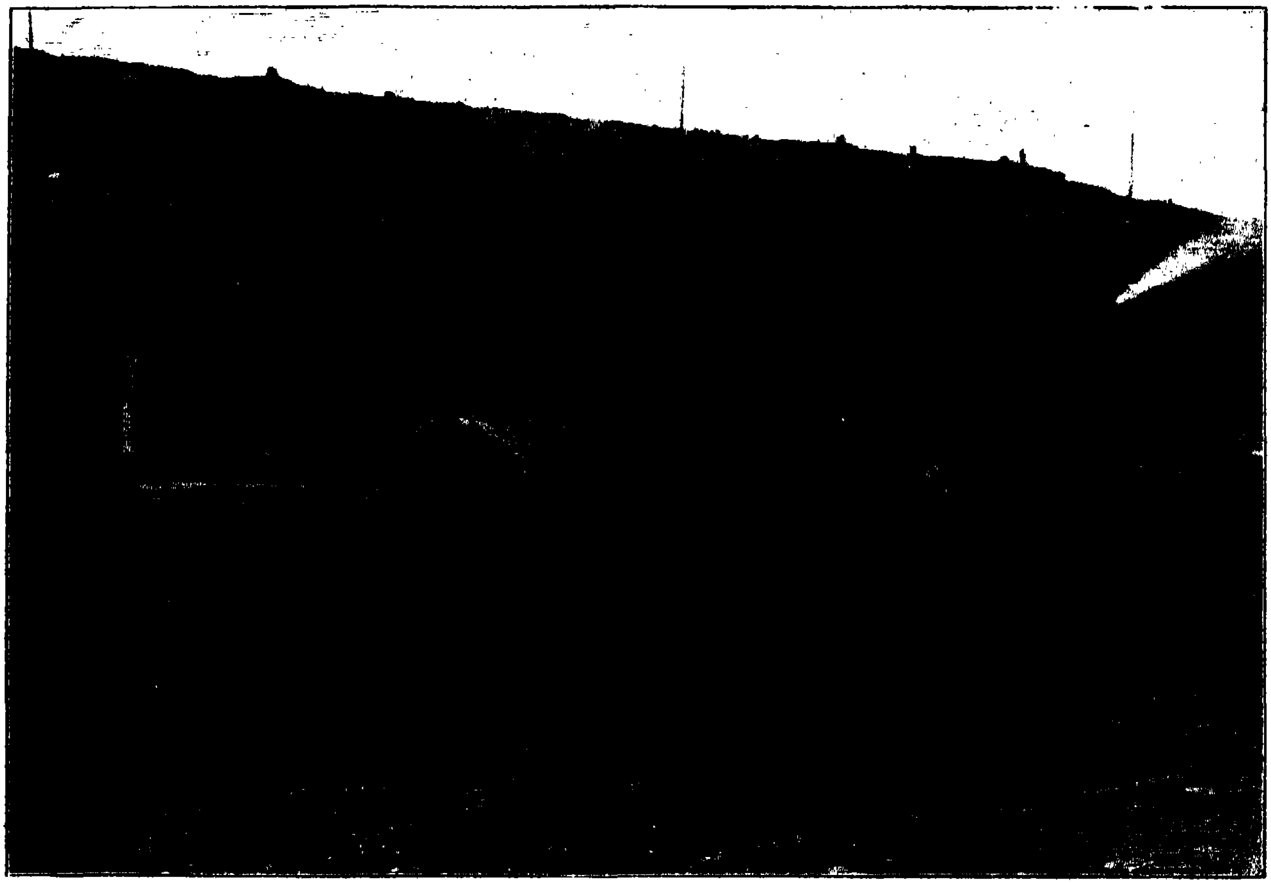
Sir Erasmus Ommanney expressed his high appreciation of the work done by Sir M. Conway and Mr. Garwood, and of the manner in which the results had been presented.

Dr. J. W. Gregory agreed in the main with Prof. Bonney, holding that though the phenomenon alluded to was no doubt a true cause, it was very uncertain whether it were a primary one.

Sir Henry Howorth considered that Sir M. Conway's theory had at least this in its favour—that it was consistent both with the laws of physics and of ice. He called attention to the change of climate which Spitsbergen has undergone in recent geological times, and to the fact of its belonging to the area of land rising in level around the North Pole.

THE LAKE SUPERIOR IRON ORE REGION.

AT the present time the conditions and prospects of American competition in the iron trade call for very serious consideration. The aggregate value of iron and steel exported from the United States to Great Britain and the continent is now considerable, the official figures for the first nine months of 1897 giving a value of 45,693,000 dollars, as compared with 34,549,000 dollars for the corresponding period of 1896. With this increase in the exports, there was a decrease in the imports from 16,361,000 dollars in the first nine months of 1896 to 10,032,000 dollars in the corresponding period of 1897. The rapidly increasing intensity of American competition is thus apparent. The exportation of iron and steel is not a result merely of depressed conditions in the United States, but of lower cost of production, brought about by enforced economy in labour, by the great discoveries of cheaply worked ore, and by the increased efficiency of the mining and metallurgical plant in use. Undoubtedly the greatest advantage possessed by the United States is that in the Lake Superior region they have the most extensive supplies of cheap and rich iron ores known to exist. It is to the sudden development and unparalleled richness of these deposits that the United States chiefly owe their cheap pig iron. It is, therefore, a matter of extreme satisfaction that an authoritative description of these deposits has been prepared by Mr. Horace V. Winchell for English readers in the form of an admirably illustrated monograph,[1] covering seventy pages of the *Transactions* of the Federated Institution of Mining Engineers, and dealing with the history, geography, geology, and mining industry of the iron-ore region. Only forty years have elapsed since the first regular mining of iron ore was begun in the district, and during that time up to January 1, 1897, the total output was as follows :—



Oliver Iron Mine, showing a face of ore 50 feet high.

Range.		First year.		Tons.
Marquette	...	1856	...	46,538,187
Menominee	...	1880	...	22,994,428
Gogebic	...	1884	...	20,788,787
Vermilion	...	1884	...	9,220,235
Mesabi	...	1892	...	8,074,583
Miscellaneous	...	...	...	2,320
Total production to date			...	107,618,540

According to the official statistics, the production in 1896 was as follows :—

Range.		Tons.		Per cent. of total.
Mesabi	...	3,082,973	..	29·18
Marquette	...	2,418,846	...	22·89
Gogebic	...	2,100,398	...	19·88
Menominee	...	1,763,235	...	16·69
Vermilion	...	1,200,907	...	11·36
Total	...	10,566,359	...	100·00

The iron-ore belts or ranges are situated chiefly in the States of Michigan and Minnesota. The beds occur in rocks of pre-Silurian, and probably of pre-Cambrian age, the determination of the geological age resting wholly on structural evidence. As to the genesis of the ores, there has been much speculation. The principal theories are (1) the obsolete one that the ores are of eruptive origin; (2) that they are mechanical sediments; and (3) that they are of chemical origin. Under the third head, the chemical action may have been that of original precipitation, or that of replacement or segregation of chemical or clastic materials by the substitution of iron oxides. Mr. Winchell inclines to the theory of oceanic precipitation advanced by him in 1889. He considers, however, that there is no reason to suppose that all the iron-ore deposits were formed in the same way.

From an engineering point of view, the Lake Superior region is remarkable for the manner in which labour-saving appliances are adopted for extracting the iron ore and for loading it into railway waggons and vessels. The result being that at the present time the mining cost is much below that at any previous period. Thus in 1890, when the Iron and Steel Institute visited the Lake Superior iron mines, the average cost of mining was 5*s*. per ton. At the present time it is 2*s*. 6*d*. per ton. In most cases the methods of mining adopted are those usual in underground mines. On the Mesabi range, however, some of the largest mines are worked as open quarries, the ore being obtained by steam shovels at a cost of 7½*d.* per ton. The accompanying illustration shows the steam-shovel method of mining at the Oliver Mine on the Mesabi range. The face of iron ore is 50 feet high, and the 90-ton steam-shovel with a 2½ cubic yard digger shown, is capable of loading 500 tons of ore per hour. It is difficult to over-estimate the value to the United States of the discovery of ore in the Mesabi Range. A producer for only four seasons, this district has in sight to-day nearly 400,000,000 tons of better ore than the average used in the United States, and perhaps 200,000 tons of ore containing 60 per cent. of iron, 0·06 per cent. of phosphorus, and 10 per cent of moisture. Indeed, Mr. Winchell thinks that it is not unreasonable to assert that the range will produce 500,000,000 tons of ore before it is abandoned.

---

[1] "The Lake Superior Iron-ore Region." By Horace V. Winchell. (Excerpt from the *Transactions* of the Federated Institution of Mining Engineers, 1897.)

At the present time the cost of a ton of Mesabi ore laid down at a Lake Erie dock is made up of the following items :—

	s.	*d.*		*s.*	*d.*
Royalty	0	0	to	1	5½
Mining cost	0	7½	to	3	1½
Railway freight	1	4	to	4	2
Lake freight	2	6	to	3	4
Insurance, commission, and loss ...	0	2½	to	0	10
Totals	4	8		12	11

There is probably no mine which has all the minimum costs, and it is evident that prices may go still lower without shutting up enough mines to produce a scarcity of ore. Mr. Winchell appends to his valuable paper a carefully compiled bibliography, tables of analyses, and statistics of shipments for the past forty-one years.

BENNETT H. BROUGH.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following is the speech delivered on March 10 by the Public Orator, Dr. Sandys, in presenting, for the honorary degree of Doctor in Science, Prof. Wilhelm Pfeffer of Leipzig, Croonian Lecturer of the Royal Society, 1898 :—

Veris adventu iam propinquo, dum terra gaudet, dum caelum avet nitescere, et arbores frondescere, nihil auspicatius ducimus quam veris quasi praenuntium quendam trans maria advectum verbis bene ominatis salutare. Salutamus praeceptorem insignem, qui rerum naturae pulcherrimam nactus provinciam, discipulos ex omni orbis terrarum parte affluentes docet, qua lege lilia crocique calyces suos explicent ; quo admonitu flores, alii solis calore, alii solis lumine adducti, se aperiant ; arte quali *mimosa* tactum etiam mollissimum reformidet frondesque teneras in sese contrahat ; artificio quam admirabili etiam vites, natura caducae, claviculis suis adminicula quaedam tamquam manibus complectantur, et quasi animantes a terra sese altius erigant. Quam dilucide demonstrat, quicquid terra gignit, secundum ea quorum in medio vivit, velut ipsos animantes, naturam suam sensim variare ac mutare. Idem neque per membranam tenuissimam aquae sorbendae rationem, quae *osmosis* dicitur, neque cellularum motum, qui *chemotaxis* nuncupatur, inexploratum reliquit. Etiam animalium minutissimorum quae *bacteria* nominantur motus varios quam subtiliter moderatur, et in ipsum exitium quam insidiose pellicit. Nuper a Societate Regia Londinensi in Britanniam vocatus, propediem (nisi fallor) ostendet, in eis rebus quas terra gignit, quinam sit ipse motus fons et origo ; quo potissimum modo sucus ipse quem e terra trahunt, spiritus ipse quem e caelo hauriunt, quasi vim quandam mittat liberam, unde motuum inter se diversorum varietas tam magna exoriatur. Quid est in his omnibus, Academici, (ut Ciceronis utar verbis) "quid est, in quo non naturae ratio intellegentis appareat"?

Praesento vobis scientiae botanicae praeceptorem illustrem, Professorem Lipsiensem, WILLELMUM PFEFFER.

MR. WILLIAM HOULDSWORTH, Rozelle, Ayr, has just intimated his intention of presenting to the University of Glasgow a sum of 5600*l.*, so invested as to yield an annual income of 150*l.*, in order to endow a research studentship in connection with the Faculty of Science. The sum of 120*l.* is to be paid annually to the research student on the foundation, the remainder to be used to defray laboratory expenses and materials in connection with his work, and the fees of such science classes as he may attend. To be eligible for appointment candidates must have studied at least two years in the University of Glasgow, and the appointment is to be made in the manner laid down by the ordinance regarding research students and fellows. The period of tenure is to be two years, during which the holder must prosecute research studies in the Natural Philosophy department with diligence and regularity. Mr. Houldsworth has taken this method of showing his interest in the welfare of the University and the advancement of science, and his recognition of the distinguished services rendered to scientific research by Lord Kelvin during a professorship of fifty years.

THE London University Commission Bill passed through Committee of the House of Lords on Thursday last. The Duke of Devonshire announced that the names of the Commissioners were the same as those in the Bill of last year with one exception, and were as follows :—Lord Davey (chairman), the Bishop of London, Sir William Roberts, Sir Owen Roberts, Prof. Jebb, M.P., Prof. Michael Foster, and Mr. E. H. Busk (chairman of Convocation). It was agreed that the powers of the Commissioners should continue till the end of 1899 instead of 1898. With the object of securing for the Agricultural College of Wye, established by the County Councils of Surrey and Kent, the advantages derivable under the Bill, Lord Stanhope moved an amendment to the clause referring to the powers and duties of the Commissioners, and he was supported by Lord Ashcombe and Lord Thring. The amendment was not pressed on a promise being given by the Duke of Devonshire that if it were found to be possible without injuriously disturbing the compromise embodied in the Bill he would endeavour on the report to insert words to meet the claims of Wye College.

REPLYING to a question asked by Lord Norton in the House of Lords on Thursday last, the Duke of Devonshire said he hoped the Bill of the Government relating to secondary education would be introduced after Easter. He added : "It is not, and never has been, the intention of the Government to do anything in the nature of what may be called establishing secondary education all over the country. Any measure which we propose will be solely for the purpose of organising in a better way that which already exists, and, possibly, for supplementing it to a certain extent. That what is being done by county authorities, or municipal bodies, or private individuals is something to be done by the Government, is not an idea which has ever been entertained by the Government. No doubt a certain amount of the 800,000*l.* which has been given to be principally expended on technical education may have been at the outset misapplied, and perhaps a certain portion of it has been wasted ; but, on the other hand, I believe that a very large portion of it is now being most usefully employed, and with very great advantage, to the various localities. It is not dependent entirely upon the will and pleasure of the County Councils. Almost every County Council has, for the purpose of administering this grant, established an educational committee, which does not usually consist solely of members of the County Council, or need not consist solely of members of County Councils. Those bodies are gradually acquiring a great deal of experience, and I believe that in a great many centres they are at present doing very valuable work."

SCIENTIFIC SERIALS.

IN the January number of the *Quarterly Journal of Microscopical Science*, Mr. E. A. Minchin gives a valuable addition to our knowledge of asconid sponge morphology in a paper on the origin and growth of the triradiate and quadriradiate spicules in the family Clathrinidæ. Mr. Minchin here produces full histological evidence of his discovery of the composite origin of these two kinds of spicules ; he shows that the triradiate spicules are formed by trios of dermal cells which immigrate from the epithelium to the interior ; by the division of each cell a sextet is formed, and the spicule appears with each of its rays corresponding to two sister cells of the sextet. With regard to the quadriradiate spicules the three basal rays develop exactly as do the triradiate spicules, but the fourth or gastral ray is secreted by a mother cell derived from a porocyte. The spicules are crystalline as a whole, but the rays are non-crystalline so long as they are distinct from one another, and may remain so for some little time after union has taken place ; the crystallisation appears to start from the secondary deposit which unites the rays at the centre. Much skill and care have been bestowed on the beautiful drawings illustrating these researches, and they are admirably reproduced in an excellent series of plates.—Prof. MacBride, in a paper on the early development of Amphioxus, shows the similarity between the cœlomic chambers of Amphioxus and Balanoglossus, and homologises the metapleural lymph canals of the former with portions of the collar pouches of the latter; in consequence of this he revives Bateson's comparison of the atrial folds of Amphioxus with the posterior collar folds of Balanoglossus.—Mr. Shipley gives an account of a new Tapeworm from a bird in the Sandwich Islands.—Dr. Willey gives the diagnosis of a new genus of Enteropneusta.—Prof. Haswell describes a Turbellarian from deep wells in New Zealand.—Prof. Ray Lankester, in a note on the development of the atrial chamber of Amphioxus, corrects Prof. MacBride's statements with regard to the well-known researches by himself and Dr. Willey on the development of the atrial chamber.

Bulletin of the American Mathematical Society, February.—The number opens with an account of the fourth annual meeting of the Society on December 29, 1897. After the election of the new Council—Prof. S. Newcomb being re-elected President—eleven papers were presented; of some of these abstracts are given, and the journals in which they have appeared, or will appear, are named.—Prof. Woodward's paper on the differential equations defining the Laplacian distribution of density, pressure, and acceleration of gravity in the earth presents an improved mathematical method for the treatment of the problem, previous methods being deemed by the author to be lacking in elegance and compactness.—The following are to appear in the *American Journal of Mathematics*—viz. on some points of the theory of functions, by Prof. Chessin; and point-transformation in elliptic coordinates of circles having double contact with a conic, by Dr. Lovett. A second paper by Dr. Lovett, entitled "Certain invariants of a plane quadrangle by projective transformation," will be published in the *Annals of Mathematics*. It is a contribution to the theory of a system of 4-coplanar points, and shows among other things how the group theory may be made to yield the details of elementary geometry.—Prof. Newcomb's presidential address, given *in extenso*, treats of the philosophy of hyperspace. "There is a region of mathematical thought," he remarks, "which might be called the fairyland of geometry. The geometer here disports himself in a way which, to the non-mathematical thinker, suggests the wild flight of an unbridled imagination rather than the sober sequence of mathematical demonstration." He defines his hyperspace as being, in general, space in which the axioms of the Euclidean geometry are not true and complete. Curved space and space of four or more dimensions are completely distinct in their characteristics, and must therefore be treated separately. Prof. Newcomb's views have already been stated in our columns, and the present address is an interesting sequel to them up to date.—Another of the papers, viz. orthogonal group in a Galois field, by Dr. L. E. Dickson, is also given here. The term *orthogonal*, in the present connection, is defined, and a remark of Jordan's shown to be not exact (*Traité des Substitutions*, p. 169, *ll.* 18-21).—We can merely mention that the second meeting of the Chicago Section was held on December 30 and 31, 1897, at which twenty-one papers were read. Brief abstracts are given. From the *Notes* we learn that in the year 1897 the membership of the Society increased from 280 to 301, and the total number of papers read was 88!

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 27.—"On the Zoological Evidence for the Connection of Lake Tanganyika with the Sea." By J. E. S. Moore, A.R.C.S.

The results of the morphological examination of the animals obtained during the author's recent expedition to Lake Tanganyika have made it evident that the fauna of this lake must be regarded as a double series, each half of which is entirely distinct in origin and nature from the other. The remarkable Molluscan shells which were brought home by Burton and Speke, form but a small part of the Molluscan section of the more abnormal of these fresh-water stocks. Besides Molluscs, the lake was found to contain fishes, Crustacea, Cœlenterata, and Protozoa, all of which, like Speke's shells, present the most curious marine affinities, and for distinctive purposes the individual members of this unique assemblage of quasi-marine fresh-water organisms are described as members of the Halolimnic group.

The distribution of the aquatic faunas occurring in Lakes Shirwa, Nyanza, Kela and Tanganyika, all of which were visited and dredged during the expedition, shows (together with what is already known respecting the Victoria Nyanza and the more northern lakes) that the Halolimnic animals are exclusively restricted to Tanganyika. It is thus rendered inconceivable that the Halolimnic forms can have arisen through the effect of ordinary conditions operating upon the population which the lake originally possessed. For the same reasons, it becomes equally clear that the Halolimnic animals cannot be regarded as the survivors of an old fresh-water stock. Since, if we accept either of these suppositions, we are bound by the facts of distribution to believe, also, that the Halolimnic animals have been destroyed in every African lake but one; a supposition which may be ingenious, but which, when the number of lakes existing in the African interior is fully realised, becomes grotesque.

Apart from the physical difficulties which the present effluent of Tanganyika presents to the ingress of organisms from the sea, it is impossible to regard the Halolimnic forms as having recently transmigrated thither from the ocean, since none of these animals are exactly similar to any marine organisms at present known. They must, therefore, have been in Tanganyika long enough to modify into their present condition from the living oceanic species which we know, or they retain the characters of a sea-fauna that has elsewhere become extinct.

The delicate nature of the lake Medusæ, and the fact that most of the Halolimnic Molluscs are exclusively deep-water forms, renders it impossible that these organisms can have made their way into Tanganyika at any time under the physical conditions which now exist.

The facts of distribution and the general characters of these forms, as well as the geographical conditions of the lake in which they are now found, lead then to the conclusion that the Tanganyika region of Central Africa must have approximated to a deep arm of the sea in ancient times.

This view is finally confirmed by the details of the anatomy of the Halolimnic animals themselves. For some of the individual Molluscs of this group combine the characters of several of the most modern marine genera. The Halolimnic fauna of Tanganyika, therefore, cannot represent an extinct fresh-water stock, since the characteristic fresh-water organisms of the present day (which would in such a case have to be regarded as their linear descendants) possess the anatomy of vastly older types.

To the Halolimnic animals there thus attaches the unique interest that they themselves constitute the few surviving indications of an old sea which once extended far into the African interior, and which, judging from the characters of the animals it left behind, must have retained its connection with the ocean at least as late as Tertiary times.

These conclusions, it will be observed, are directly in opposition to the views which were originated by Murchison, and which depict the African interior as never having been below the sea at least since the New Red Sandstone age.

February 17.—"On the Magnetic Deformation of Nickel." By E. Taylor Jones, D.Sc.

The experiments were made with a view to further testing a result arrived at on a former occasion by the author, viz. that the magnetic contraction of a long nickel wire was approximately proportional, when allowance was made for the effects of Kirchhoff's system of stresses, to the fourth power of the magnetisation.

In order to vary, if possible, the conditions of the experiments some preliminary measurements were made to find out whether temperature had any marked influence on the magnetic contraction. The temperature of the specimen was raised by allowing warm water to flow through the water-jacket of the magnetising coil. It was found that at low field-strengths (up to about 90 C.G.S.) the magnetic contraction was greater at 56° C. than at 19° C.; at higher fields the contraction was greater at the lower temperature, the difference being about 6 per cent. at the field 330 C.G.S.

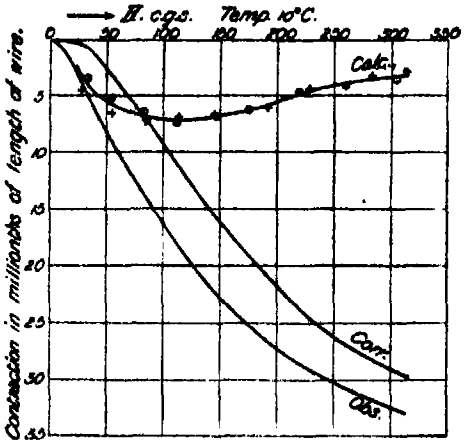
Repeated measurements showed that the contraction at any temperature and field was not constant, but diminished as time went on. In order to eliminate this effect as far as possible the subsequent measurements were made in the following order:—

(1) The change of magnetisation accompanying a certain increase of tension, and the magnetisation at the mean tension (at 10° C. and 55° C.).

(2) The magnetic contraction at the mean tension (at 10° C. and 55° C.).

(3) The measurements of (1) repeated.

(4) The magnetic contraction at 10° C. Values of the expression deduced from Kirchhoff's theory were calculated from (1) and (3) for both temperatures, and the mean compared with the observed contraction (2). The results are shown (for 10° C.) in the accompanying diagram. The calculated contraction is much less than the observed, and the difference is approximately proportional to the *sixth* power of the magnetisation. A similar result was obtained by comparing the mean observed contraction at 10° C. (2) and (4), with the calculated value deduced from (3). All the quantities measured showed a diminution as time went on, especially the influence of tension on magnetisation at low fields. The calculated values of the contraction deduced from (1) are indicated in the diagram by the points + + + . . . ; those deduced from (3) by the points ⊙ ⊙ ⊙ . . . At the field 275 C.G.S. the magnetic contraction was about 16 per cent. less than it was four months earlier.



Physical Society, March 11.—Mr. Shelford Bidwell, President, in the chair.—Prof. J. D. Everett gave a communication on dynamical illustrations of certain optical phenomena. The first part of the paper deals with the properties of a series of equal particles attached at equal intervals to an uniform stretched elastic weightless string. Their free simple-harmonic modes of wave-motion are first investigated. The highest frequency occurs when the wave-length is double that of the common distance a. As the wave-length increases from $2a$ to infinity, or diminishes from $2a$ to a, the frequency tends to zero. To every wave-length λ_1 between $2a$ and infinity, there corresponds a wave-length λ_2 between $2a$ and a, such that $a/\lambda_1 + a/\lambda_2 = 1$. The frequency is the same for λ_2 as for λ_1. Further examination shows that the difference of wave-length between these two solutions is only apparent, and that, so far as the movements of the particles are concerned, waves of length λ_1 travelling in one direction, are identical with waves of length λ_2 travelling in the opposite direction. The same is true if $a/\lambda_1 + a/\lambda_2$, instead of being unity, is equal to any integer. On the other hand, if the difference between a/λ_1 and a/λ_2 is an integer, the two sets of waves travel in the same direction. Any simple-harmonic wave-motion of the system of particles may thus be regarded as having any one of an infinite number of wave-lengths. When one particle of the system is constrained to a S.H. motion, of frequency not exceeding that which corresponds to $\lambda = 2a$, the whole system will ultimately vibrate in equal waves. When the frequency of the constrained particle exceeds that due to $\lambda = 2a$, the ultimate state will be S.H. motion with exact opposition of phase between successive particles. The simultaneous displacements of the particles at any instant, as we travel away from the constrained particle in either direction, form a diminishing geometrical progression with signs alternately plus and minus. Expressions are investigated for the constraining force and for the ratio of the energy of the system (consisting of an unlimited number of particles) to the energy of the constrained particle. The second part of the paper deals with pendulums. (1) Sympathetic pendulums, such as two equal pendulums suspended from the same support. (2) Double pendulums, *i.e.* one simple pendulum suspended from another. In each case the investigation consists in seeking a mode of vibration in which the two bobs have either identical or opposite phases, so that their displacements are in a constant ratio, positive or negative. In every case there are two such modes, one with a positive and the other with a negative ratio. As regards the sympathetic pendulums: when they are equal in mass and length, the periods for the two modes are approximately equal, and the displacement of each pendulum follows the law of a "curve of beats," the excursions are largest for one pendulum when they are smallest for the other. As regards the double pendulum: when the lower mass is much less than the upper, there exist, in like manner, motions following the law of beats, provided that, to start with, one bob is at rest in the zero position, and the other at rest in an extreme position. If the lengths of the two strings are decidedly unequal, one fundamental mode has approximately the period of the upper, and the other the period of the lower pendulum. In the former, the displacements of the two bobs are comparable; in the latter, the displacement of the upper is small compared with the lower. The bearing of these conclusions is pointed out, first, on Lord Kelvin's conclusions respecting a suspended clock; and, secondly, on Lord Rayleigh's assertion (frequently quoted in connection with anomalous dispersion) respecting the influence on a heavy pendulum of a much lighter one suspended from it. To obtain the phenomenon of beats in perfection, the upper string must be slightly longer than the lower, and the ratio of *difference* to *sum* of lengths must equal the ratio of lower mass to upper. The beats thus obtained explain the experiment described in the second edition of "Rayleigh on Sound," § 62. Sellmeier's application of the beats of double pendulums to explain fluorescence is briefly described. Stokes explains fluorescence by the analogy of the chain of equal particles discussed in the first part of the paper. Forced vibrations quicker than the critical frequency are produced by the action of the vibrating ether on the fluorescent body; and when the body is left to itself, its subsequent motion is made up of S.H. components, all of which are below the critical frequency.—Prof. R. A. Lehfeldt then read a paper on the properties of liquid mixtures. In a previous communication (*Phil. Mag.* 5, vol. xl. p. 398) the author followed out the consequences of a certain thermodynamic relation between the composition of a liquid mixture and that of the vapour in equilibrium with it, and the saturation-pressure of the system. More stable compounds are now chosen, viz. benzene and toluene mixed with carbon tetrachloride, as types of normal organic compounds; and benzene and toluene mixed with ethyl alcohol as types of a so-called "associated" liquid. These experiments have been carried out in the Davy-Faraday laboratory. The measurements come under two distinct groups: (1) vapour-pressure, (2) composition of vapour. They were made separately, on material from the same source, prepared identically. To measure the vapour-pressure of the mixtures, the "dynamic" method was adopted. An experiment consists in weighing out a mixture, taking its refractive-index by a Pulfrich refractometer, placing it in a boiling tube, and after adjusting temperature and pressure, taking observations at different temperatures on a rising scale, and then on a falling scale. The refractive-index of the residue is again measured; this is always used for checking the composition of the mixtures. For determining the composition of the vapour over liquid mixtures, the method used is to distil a little of the mixture and analyse the distillate. The apparatus is arranged so that the distillate can be drawn off by a tap, as required. The author criticises the results of Linebarger (*Jour. Amer. Chem. Soc.*, vol. xvii.), and also those of Margules (*Wien. Ber.*, vol. civ.). Linebarger states that the partial pressure of benzene and toluene in mixtures, is simply proportional to the molecular percentage present. This conclusion, the author considers, is only roughly true; the partial pressure of the hydro-carbon vapour is not necessarily linear in mixtures; hence, the rule proposed by Linebarger for determining the molecular weight is incorrect.—The President proposed votes of thanks to the authors, and the meeting was adjourned until March 25.

Chemical Society, March 3.—Prof. Dewar, President, in the chair.—The following papers were read:—Preparation of anhydrous hydrogen cyanide and carbon monoxide, by J. Wade and L. C. Panting. On dropping a mixture of equal volumes of sulphuric acid and water on to 98 per cent. potassium cyanide, hydrogen cyanide is evolved in nearly theoretical amount; with concentrated sulphuric acid, nearly pure carbon monoxide is evolved in almost theoretical quantity.—Preparation of some nitro- and amido-oxylutidines, by J. N. Collie and T. Tickle. The authors have prepared mononitro- and monamido-derivatives of pseudolutidostyril and ethylic pseudolutidostyrilcarboxylate by the ordinary methods.—Production of some nitro- and amido-oxylutidines. Part ii., by Miss L. Hall and J. N. Collie. Nitrolutidone is obtained by nitrating lutidone with a mixture of nitric and sulphuric acids; the platinichloride of amidolutidone, when warmed with hydrochloric acid, seems to yield a salt of propine diamine, $CMe(NH_2):CH(NH_2)$.—On benzene hexabromide, by F. E. Matthews The author was unable to prepare the second benzene hexabromide described by Orndorff and Howells, and could not prepare either the hexachloride or hexabromide of bromobenzene.—Note on the action of bromine on benzene, by J. N. Collie and C. C. Frye. The authors have succeeded in proving the presence of ortho-compounds in the product of the action of bromine on benzene in presence of sunlight.—Note on manganic salts, by C. E. Rice. The author shows that the decomposition of manganic chloride in solution into manganous chloride and chlorine is reversible.—Some chemical properties of concentrated solutions of certain salts. Part i. Potassium carbonate, by W. C. Reynolds. By crystallising a concentrated solution of potassium carbonate containing the chloride, nitrate, or acetate of various metals, the author has obtained crystalline double salts of the following compositions: $CuK_2(CO_3)_2$, $CuK_2(CO_3)_2, H_2O$, $CuK_2(CO_3)_2, 4H_2O$, $MnK_2(CO_3)_2, 4H_2O$, $FeK_2(CO_3)_2, 4H_2O$, $CaK_2(CO_3)_2$, $Bi_2OK_4(CO_3)_4, H_2O$, $CoK_2(CO_3)_2, 4H_2O$, $NiK_2(CO_3)_2, 4H_2O$, $MgK_2(CO_3)_2, 4H_2O$, and $AgKCO_3$.—The colouring matters of the Indian dye-stuff *Delphinium zalil*, by A. G. Perkin and J. A. Pilgrim. The dried flowers and stems of *Delphinium zalil* are used in India under the name of "asbarg" for producing a yellow colour on alum-mordanted fabrics. Three colouring matters exist as glucosides in the plant, namely isorhamnetin, quercetin, and a third which was not obtained pure.—Some metallic salts of natural yellow colouring matters, by A. G. Perkin and P. J. Wood. Quercetin, morin, fisetin and myricetin decompose potassium acetate in alcoholic solution with formation of sparingly soluble metallic derivatives; luteolin, apigenin, chrysin and gentisin do not do so.—The interaction of magnesium and solution of copper sulphate, by E. Divers.

Royal Microscopical Society, February 16.—Mr. A. D. Michael, Vice-President, in the chair.—Mr. J. E. Barnard said that when he gave his demonstration at the November meeting, on the application of the electric arc to photomicography, Mr. Nelson suggested that it would be of interest if he would show some lantern slides taken in that way; he had accordingly brought a few examples for exhibition on the screen. These included a series showing ringworm fungi, which he thought would have some interest apart from the method by which the photographs had been produced. A number of slides were then shown, illustrating the appearance of the fungi in various stages and under conditions in which the external portions, or internal structure of the hair of man and animals had been attacked, and their appearance when cultivated artificially. The photographs were from microscopical preparations lent by Dr. T. Colcott Fox. Other slides were shown of the bacilli of anthrax, tuberculosis, typhoid fever, bubonic plague, &c. Dr. Hebb concluded some remarks by saying that he did not know that he had ever seen these subjects so beautifully illustrated as he had that evening. Mr. T. Charters White said he could endorse all that fell from Dr. Hebb. For high amplification he did not know that he had seen anything so sharply defined, especially in the case of the Podura scale magnified 6000 diameters. The Chairman said no one could fail to be struck by the clear manner in which these minute objects had been shown. [Two of the pictures, with a short account of the light used in their production, have already appeared in these columns (p. 448).—Mr. T. Charters White read a paper on microcrystallography, which he illustrated by the exhibition on the screen of a number of slides of the crystals described. He had selected them to show how large a number of beautiful forms might be obtained from the same salt by causing it to crystallise under different conditions. Mr. White further illustrated the subject by exhibiting the formation of crystals under the microscope. The Chairman thought it quite possible that when they came to examine these crystals very carefully they would find that the ultimate form did, after all, agree with the typical form, but it was remarkable to see how other forces could modify these forms.—The Chairman said they had another paper on the agenda, on Foraminifera taken chiefly from shallow water in the Malay Archipelago, by Mr. Durrand.

Royal Meteorological Society, February 16.—Mr. F. Campbell Bayard, President, in the chair.—Mr. E. Mawley gave a report on the phenological observations for 1897, from which it appeared that there had been a marked absence of very exceptional weather during the past phenological year, the most noteworthy features affecting vegetation being the persistent rains in March and the three dry periods of May, July and October. Until about the middle of May wild plants appeared in blossom in advance of their usual time, but throughout the rest of the flowering season they were all somewhat behind their average dates in coming into bloom. The heavy rainfall in the early spring favoured the hay, which proved the only really abundant farm crop of the year, but greatly impeded the sowing of spring corn. The cereals were, however, much benefited later on by the warm, dry and brilliant weather of the summer. Taking the country as a whole, oats proved a good crop, barley an average one, while the yield of wheat was somewhat under average. There were also fair crops of roots and potatoes. It was owing more to the dry spring and summer and the sunless autumn of the previous year, than to the moderate frosts and cold winds of the spring of 1897, that the fruit crop was such a very light one. Apples, pears and plums, and especially the latter, yielded badly, while the small fruits were in most districts only average crops.—Mr. Hopkinson read a paper on monthly and annual rainfall in the British Empire 1877–96. In this the author gave particulars of the mean monthly and annual rainfall, and the number of rainy days, at the following twelve stations in the British Empire, viz. London, England; Port Louis, Mauritius, Calcutta and Bombay, India; Colombo, Ceylon; Adelaide and Melbourne, Australia; Wellington, New Zealand; Toronto and Winnipeg, Canada; Kingston, Jamaica; andMalta.

Linnean Society, February 17.—Dr. A. C. L. Günther, F.R.S., President, in the chair.—Dr. Kakichi Mitsukuri, Professor of Zoology, Imperial University, Tokyo, was admitted a Foreign Member.—Prof. G. B. Howes, F.R.S., exhibited specimens of Dog-fishes: (1) *Scyllium canicula* from the egg-case, and (2) *Scyllium catulus* prematurely hatched, which he had received from Mr. C. W. L. Holt, of the Marine Biological Laboratory at Plymouth. The specimens showed the dorso-lateral and caudal placoids which led Filippi to propose the species *Scyllium acanthonotum*, shown by Dr. Günther to be based upon a developmental character, and had in recent years been the subject of some interesting speculations by Paul Meyer. For comparison he exhibited also an embryo from the purse of *Callorhynchus antarcticus*, showing a similar set of organs, and gave reasons for surmising that they are not merely transitory vestiges, but of service to the animal while encapsulated within its egg-case. Some additional remarks were made by the President.—Mr. J. E. Harting exhibited a nearly white variety of *Mus rattus* recently obtained in Carnarvonshire, and made some remarks on the difference of haunts and habits in the two species *M. rattus* and *M. decumanus*, and on their usual antagonism. In reply to Mr. H. J. Elwes on the question of occasional hybridism, he stated that no well-established case of the kind had been recorded, although some years ago Mr. Barrett Hamilton had described (*Zool.*, 1888, p. 141) a suspected hybrid which was partly brown in colour, partly black, and exhibited some other intermediate characters. He referred to the so-called Irish rat, *Mus hibernicus* of Thompson, which was now regarded as a permanent black variety of *Mus decumanus* not confined to Ireland.—Mr. F. N. Williams read a paper on *Arenaria*, one of the larger genera of Caryophyllaceæ, which now includes a considerable number of species. *Alsine* and others, usually included as sections of the genus, he thought should be regarded as distinct genera; *Alsine* and *Arenaria* being distinguished by the same cardinal character which separates *Lychnis* from *Silene*.—Mr. G. S. West read a paper on the histology of the salivary, buccal, and Harderian glands of the *Colubridæ*, with notes on their tooth-succession and the relationship of the poison-duct.

Geological Society, February 23.—W. Whitaker, F.R.S., President, in the chair.—On some submerged rock-valleys in South Wales, Devon, and Cornwall, by T. Codrington. The author described various valleys in which the solid rock was reached at a considerable depth below sea-level, on the sides of Milford Haven and in the Haven itself; beneath the Tivy, Tawe, and Neath, the Wye, the Severn, the Bristol Avon, the Dart, the Laira, the Tavy, the Tamar, and other rivers. In the case of the Dart the rock-bottom had been found at one place at a depth of 110 feet below low-water level, and in the case of other rivers at varying depths less than this. The deposits showed that some of the infilling took place after the period of submerged forests, and much before this, for frequent cases of glacial deposits filling the bottoms of these submerged valleys were recorded. The fact that in the Solent and Thames the glacial deposits bordered the sides of the valleys, and did not occur at the bottom as in the case of the valleys described in the paper, indicated that the latter were older than the former, though they presented features similar to those of some of the valleys of the North-east and North-west of England.—Some new carboniferous plants, and how they contributed to the formation of coal-seams, by W. S. Gresley. The author, in a paper published in abstract in the Society's *Quarterly Journal* for May 1897 (vol. liii. p. 245), argued that certain brilliant black laminæ in coal, and similar materials found among some mechanical sediments of the coal measures, pointed to the former existence of an aquatic plant. In the present communication he described structures in the pitch-coal laminæ of bituminous coal and in the glossy black layers of anthracite which he believed to be indications of two other kinds of plants, and stated that he had examined structures which might be due to some other kinds of vegetation.

Zoological Society, March 1.—Dr. W. T. Blanford, F.R.S., in the chair.—Mr. G. A. Boulenger, F.R.S., exhibited, and made remarks upon, a living hybrid newt, the result of a cross between specimens of a hybrid *Molge cristata* × *M. marmorata* and the former species, which had been reared at Argenton-sur-Creux by M. R. Rollinat.—Mr. F. E. Beddard, F.R.S., read a paper on certain points in the anatomy of the cunning Bassarisc (*Bassariscus astutus*), as observed while dissecting a specimen which had died in the Society's menagerie, and called special attention to certain points in the viscera and in the form of the brain in which *Bassariscus* agreed with the arctoid carnivora.—Mr. G. A. Boulenger, F.R.S., read a paper entitled "a revision of the African and Syrian fishes of the family *Cichlidæ*, part I." The author had come to the conclusion that the African and Syrian fishes of this family were, so far as was known, represented by nine genera.—A communication was read from Prof. B. C. A. Windle and Mr. F. G. Parsons containing the second part of a memoir on the myology of the terrestrial carnivora. The present portion dealt with the muscles of the hind limb and the trunk in various species, which, in many cases, seemed to give good indications of their affinities.—A communication from Dr. A. G. Butler on the Lepidoptera collected by Mr. G. A. K. Marshall in Natal and Mashonaland in 1895 and 1897 was read.

PARIS.

Academy of Sciences, March 7.—M. Wolf in the chair.—Chemical actions exerted by the silent discharge. Aldehydes and nitrogen, by M. Berthelot. Mixtures of nitrogen with various substances of aldehyde function, including acetaldehyde, propionic aldehyde, acetone, methylal, aldol, paraldehyde, trioxymethylene, formaldehyde, camphor, benzaldehyde, salicylic aldehyde, and furfurol were submitted to the action of the silent discharge for periods varying from eight to twenty-four hours. The nitrogen absorbed was measured, and the gases produced analysed. The solid and liquid products were not obtained in quantities sufficient for analysis.—Chemical action of the silent discharge. Organic acids and nitrogen, by M. Berthelot. The acids studied were formic, acetic, propionic, crotonic, benzoic, succinic, maleic, fumaric, phthalic, camphoric, glycollic, lactic, malic, tartaric, oxybenzoic, pyruvic, levulic, and dehydracetic acids.—Observations relating to the chemical action of the silent discharge on dielectric liquids, by M. Berthelot. The liquids examined were alcohol, olive oil, and essence of turpentine. Alcohol gave a mixture of hydrogen and ethane.—Action of calcium sulphate upon some haloid salts of the alkalies, by M. A. Ditte. A study of the equilibrium produced in aqueous solutions containing calcium sulphate, and varying proportions of alkaline chlorides, bromides, and iodides.—On the number and symmetry of the fibro-vascular bundles of the petiole as a measure of the perfection of vegetable species, by M. A. Chatin.—On the results given by a seismograph installed at Grenoble, by M. M. Lévy. The slight earthquake shock noticed in the valley of the Po on March 4, was clearly shown on the seismographs (Kilian and Paulin, Angot) at Grenoble.—On the absorptive power of lampblack for radiant heat, by MM. Crova and Compan. It is usually assumed that for a given flux of radiant energy the absorptive power of a layer of lampblack is equal to unity. This, however, is not necessarily the case, the coefficient of absorption varying between narrow limits according to the nature of the deposit and its mode of application. A layer of black, applied in the ordinary way, may have an absorptive power as low as 0·9. The application of several layers, each washed with alcohol and then dried, gives a more complete absorption, the coefficient after some six deposits, rising to ·98. Fewer deposits of platinum black are required to reach the same limit.—Report on a memoir of M. Gonnessiat, entitled "Researches on the law of variations of latitude," by M. Radau.—On the "Histoire celesté du 17^{e} siècle" of Pingré, by M. G. Bigourdan.—Note on the ellipsoid of Jacobi, by M. P. Krüger.—On the determination of the group of rationality of linear differential equations of the fourth order, by M. F. Marotte.—On conjugated congruences of pencils C, by M. C. Guichard.—On the invariants of linear partial differential equations of two independent variables, by M. J. Le Roux.—On a problem of Riemann, by M. Ludwig Schlesinger.—On certain first integrals of some dynamical equations in two variables; application to a particular case of the problem of three bodies, by MM. J. Perchot and W. Ebert.—Researches of precision on the infra-red dispersion of quartz, by M. E. Carvallo. The dispersion was measured by means of a bolometer; the results differ appreciably from those of Mouton, but show a remarkably close agreement with figures calculated by means of an extrapolation formula of Mace de Lépinay, derived from observations in the visible spectrum and ultra-violet.—Influence of soft iron on the mean square of the difference of potential at the extremities of a bobbin traversed by a high-frequency current, by M. H. Pellat.—On the temperature of incandescent lamps, by M. P. Janet. The variation of the resistance of the lamp as a function of the difference of potential at the ends of the filament is measured, and also the variation in the resistance of a cooled lamp as a function of the time. From these, with the weight of the filament, the temperature can be deduced, assuming that the filament is composed of pure carbon. Four lamps gave concordant figures, namely 1610°, 1630°, 1620°, and 1720° C.—Some properties of kathodes placed in a powerful magnetic field, by M. André Broca. The experiments lead to the conclusion that there are two kinds of kathode rays, one of which rotates round the line of force of the magnetic field, and the other which follows this line of force.—Researches on nickel-steel. Variations of volume of irreversible alloys, by M. C. E. Guillaume.—Researches on the magnetic properties of nickel-steel, by M. Eugène Dumont. A determination, in absolute values, of the magnetic permeability of twelve samples of nickel steel containing from 26 to 44 per cent. of nickel, in fields varying from 14 to 50 C.G.S. units, and at temperatures between − 78° and 250° C. The results are expressed graphically in three sets of curves.—Preparation of beryllium by electrolysis, by M. P. Lebeau. The pure metal is most conveniently obtained by the electrolysis of the fused double fluoride of sodium and beryllium by a current of six amperes, and potential difference of 35 to 40 volts.—Chemical estimation of carbon monoxide in the air, even in the smallest traces, by M. Maurice Nicloux. The method is based upon the fact that carbon monoxide is oxidised by iodic anhydride at 150°, giving carbonic acid and iodine, the latter, representing the carbonic oxide present, being measured by a colorimetric method.—On the dissociation of the carbides of barium and manganese, by MM. Gin and Leleux. These two carbides, at the highest temperatures of the electric furnace, behave similarly to calcium carbide; not being volatile, but dissociated into the metal and carbon.—Researches on the explosion of mixtures containing marsh gas by electric currents, by MM. H. Couriot and J. Meunier. There is no danger of explosion of mixtures of air and methane, by wires raised to incandescence by an electric current. It is only when the wire melts, and a spark passes, that an explosion is determined.—On the preparation and etherification of asymmetrical dimethylsuccinic acid, by M. E. E.

Blaise.—On the synthetical isoborneols, their identity with fenoilic alcohols, by MM. G. Bouchardat and J. Lafont.—On the partial decomposition of chloroform in the organism, by MM. A. Desgrez and M. Nicloux. A reply to the criticism of M. de Saint-Martin. Normal blood gives on analysis a small proportion of carbon monoxide. This amount is notably increased in the blood of animals under chloroform.—A true mucin produced by a fluorescent pathogenic bacillus, by M. Ch. Lepierre.—Action of the bacterium of sorbose upon polyhydric alcohols, by M. Gabriel Bertrand. Alcohols show very different behaviour when treated with the sorbose bacillus; some, such as glycol, xylite and dulcite, resisting the oxidising action completely; others, glycerine, sorbite, mannite, being readily oxidised to ketones.—Influence of the medium upon variations in the Protozoa, by M. J. Kunstler.—The larva of the sponges and homologation of the leaflets, by M. Yves Delage.—On a new type of Copepod, by M. Jules Bonnier. The new type, to which the name *Pionodesmotes phormosomæ* is given, was found by the Prince of Monaco in one of the scientific voyages of the *Princess Alice*.—On a cereal of the Soudan, by M. Dybowski.—A prehistoric station at Mount Huberville, near Valognes, by M. Le Nordez.

DIARY OF SOCIETIES.

THURSDAY, March 17.

Royal Society, at 4.30.—The Croonian Lecture will be delivered by Prof. Wilhelm Pfeffer, For. Mem. R.S. On the Nature and Significance of Functional Metabolism (Betriebs-stoffwechsels) in the Plant.

Royal Institution, at 3.—Magnetism and Diamagnetism: Prof. J. A. Fleming, F.R.S.

Linnean Society, at 8.—Natural Selection the Cause of Mimetic Resemblance and Common Warning Colours: Prof. E. B. Poulton, F.R.S.—On the Brain of the Edentata, including Chlamydophorus: Dr. Elliott Smith.—On Limnocarpus, a New Genus of Fossil Plants from the Tertiary Deposits of Hampshire: Clement Reid.

Chemical Society, at 8.—The Reduction of Bromic Acid and the Law of Mass Action: Winifred Judson and Dr. J. Wallace Walker.—The Action of Ferric Chloride on the Ethereal Salts of Ketone Acids:—Dr. R. S. Morell and Dr. J. M. Crofts.—Note on the Volatility of Sulphur: T. C. Porter.—Action of Ammonia and Substituted Ammonias on Acetylurethane: *Dr. George Young and Ernest Clark*.—*Cannabinol*: T. B. Wood, W. T. N. Spivey, and Dr T. H. Easterfield.—Formation of Oxytriazoles from Semicarbazides: Dr. G. Young, and B. M. Stockwell.

Institution of Civil Engineers, at 8.—Sixth "James Forrest" Lecture, Geology in Relation to Engineering: Prof. W. Boyd Dawkins, F.R.S.

Camera Club, at 8.15.—Some Recent Animal Photographs: Gambier Bolton.

FRIDAY, March 18.

Royal Institution, at 9.—The Bringing of Water to Birmingham from the Welsh Mountains: J. Mansergh.

MONDAY, March 21.

Society of Arts, at 8.—The Thermo-Chemistry of the Bessemer Process. Prof. W. N. Hartley, F.R.S.

Victoria Institute.—A New Babylonian Story of the Flood: Theo. G. Pinches.

Camera Club, at 5.30.—Annual General Meeting.—At 8.30.—Travels in Kashmir and Little Tibet: Dr. Arthur Neve.

TUESDAY, March 22.

Royal Institution, at 3.—The Simplest Living Things: Prof. E. Ray Lankester, F.R.S.

Institution of Civil Engineers, at 8.—Calcium Carbide and Acetylene: Henry Fowler.—Extraordinary Floods in Southern India: their Causes, and Destructive Effects on Railway Works: E. W. Stoney.

Royal Horticultural Society.—Horticultural Soils.

Royal Photographic Society, at 8.—The Gum Bichromate Process: Robert Demachy.

WEDNESDAY, March 23.

Society of Arts, at 8.—The Preparation of Meat Extracts: C. R. Valentine.

Geological Society, at 8.—The Eocene Deposits of Devon: Clement Reid.—On an Outlier of Cenomanian and Turonian near Honiton, with a Note on *Holaster altus*, Ag.: A. J. Jukes-Browne.—Cone-in-Cone: Additional Facts from various Countries: W. S. Gresley.

THURSDAY, March 24.

Royal Society, at 4.30.—The Bakerian Lecture will be delivered by Dr. W. J. Russell, F.R.S. Subject: *Further Experiments on the Action exerted by certain Metals and other Bodies on a Photographic Plate*.

Royal Institution, at 3.—Recent Researches in Electricity and Magnetism: Prof. J. A. Fleming, F.R.S.

Institution of Electrical Engineers, at 8.—Cost of Generation and Distribution of Electrical Energy: R. Hammond.

Camera Club, at 8.15.—Photographic Engraving in Intaglio: Colonel Waterhouse.

FRIDAY, March 25.

Physical Society, at 5.—On the Circulation of the Residual Gaseous Matter in a Crookes' Tube: A. A. Campbell Swinton.—On some Improvements in the Roberts-Austen Recording Pyrometer, and Notes on Thermo-electric Pyrometers: A. Stansfield.

Institution of Civil Engineers, at 8.—Internal Governor Friction H. O. Eurich.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Évolution Individuelle et Hérédité: F. Le Dantec (Paris, Alcan).—Ethnological Studies among the North-West Central Queensland Aborigines: W. E. Roth (Brisbane, Gregory).—Exploration of the Air by means of Kites (Cambridge, Mass., Wilson).—Queen's College, Galway, *Calendar for 1897–98 (Dublin, Ponsonby)*.—*Prospecting for Minerals*: S. H. Cox (Griffin).—Lehrbuch der Algebra: Prof. H. Weber, Zweite Auflage, Erster Band (Braunschweig, Vieweg).—The Collected Mathematical Papers of Arthur Cayley. Supplementary Volume containing Titles of Papers and Index (Cambridge University Press).—Araneae Hungariae: C. Chyzer and L. Kulczynski, Tome 1 and 2 (2 parts) (Budapestini).—Audubon and his Journals: M. R. Audubon, 2 Vols. (Nimmo).—The Smithsonian Institution, 1846–1896. The History of its First Half-Century: edited by G. Browne Goode (Washington).—Smithsonian Institution. Revision of the Orthopteran Group Melanopli (Acridiidæ): S. H. Scudder (Washington).

Pamphlets.—Field Columbian Museum. Annual Report of the Director to the Board of Trustees for the Year 1896–97 (Chicago).—Ditto. List of Fishes and Reptiles obtained by Field Columbian Museum East African Expedition to Somali-Land in 1896: S. E. Meek and D. G. Elliot (Chicago).

Serials.—Knowledge, March (Holborn).—Botanische Jahrbücher, Fünfundzwanzigster Band, 1 and 2 Heft (Leipzig).—Strand Magazine, March (Newnes).—Engineering Magazine, March (222 Strand).—Rendiconto delle Sessioni della R. Accademia delle Scienze dell' Istituto di Bologna, 1895–96: Ditto, Nuova Serie, Vol. 1, Fasc. 1 to 4 (Bologna).—Katalog der Bibliothek der K. Leopoldinische-Carolinischen Deutschen Akademie der Naturforscher, Achte Liefg., Band ii. 5 (Halle).—Journal of the Institution of Electrical Engineers, March (Spon).—Science Abstracts, January (Taylor).—Bulletin of the Liverpool Museums, February (Liverpool).

THURSDAY, MARCH 24, 1898.

A BIOGRAPHY OF WILLIAM HARVEY.

Masters of Medicine. William Harvey. By D'Arcy Power, F.S.A., F.R.C.S. Edited by Ernest Hart, D.C.L. Crown 8vo. Pp. xi + 296. (London: T. Fisher Unwin, 1897.)

THERE is probably no name in the roll of European physicians antecedent to our own time so familiarly known as that of the discoverer of the circulation of the blood. Harvey was one of the founders of the modern method of investigating nature, and he takes rank with Galileo and Descartes among the select few who stand out as landmarks in the early history of exact science. His life and work have therefore an enduring interest for all educated men. Dr. Willis's classical biography of Harvey, published twenty years ago, was not cast in a popular mould, and is now almost out of print. It was therefore time, and there was room, for a new life of Harvey; and the late Mr. Hart was fortunate in his selection of Mr. D'Arcy Power for this task. Mr. Power tells us in his preface:

> "It is not possible, nor have I attempted, in this account of Harvey, to add much that is new. My endeavour has been to give a picture of the man and to explain in his own words, for they are always simple, racy, and untechnical, the discovery which has placed him in the forefront of the Masters of Medicine."

Notwithstanding this modest disclaimer, Mr. Power has succeeded in collecting a good deal of fresh collateral information which throws much interesting side light on the career and surroundings of Harvey.

William Harvey was born in Folkestone in 1578. He was the eldest son of an opulent Kentish yeoman, and his career was never hampered by pecuniary difficulties. His school boy days were passed at Canterbury. Thence he migrated to Caius College, Cambridge, where he graduated in arts in 1597, at the age of nineteen. There were at that time no organised Schools of Medicine in Britain, and Harvey had to look elsewhere for the means of prosecuting his medical education. He chose Padua; and became a pupil of Fabricius—the foremost anatomist of his day. Fabricius was then engaged in perfecting his discovery, or rather re-discovery, of the valves of the veins. Fabricius, no doubt, demonstrated the existence of these valves to his class; and it may be inferred that Harvey's interest in the motions of the heart and blood was first awakened by these demonstrations. Fabricius taught that the purpose of these valves was to prevent over-distension of the vessels when the blood passed from the larger into the smaller veins (a double error), whilst they were not needed in the arteries because the blood was always in a state of ebb and flow. It was reserved for Harvey to point out their true use, and to indicate their importance as an anatomical proof of the circulation of the blood.

Harvey spent four years at Padua, and obtained the degree of Doctor of Medicine of that University. He then settled in London, and came rapidly to the front. At the age of twenty-nine he was elected Fellow of the College of Physicians; at thirty-one he became physician to St. Bartholomew's Hospital; at thirty-seven he was chosen Lumleian Lecturer on Anatomy to the College of Physicians. About the same time he was appointed Physician Extraordinary to James I., and subsequently Physician in Ordinary to his successor Charles I. These latter appointments gave Harvey command of the herds of deer in the royal parks, for the purpose of the vivisections and dissections which he practised in the course of his researches on the motions of the heart and blood, and in his investigations on embryology.

Harvey delivered his first course of Lumleian Lectures in 1616. It was in these lectures that he first propounded his views on the circulation of the blood, and demonstrated the anatomical and experimental evidence on which his conclusions were based. These demonstrations were, as he tells us, annually repeated at the Lumleian Lectures for nine successive years. It was only after this long probation that Harvey ventured to give his discoveries to the world. This he did in the form of a small Latin quarto of 76 pages, entitled "Exercitatio Anatomica de motu cordis et sanguinis," published at Frankfort in 1628. This little book is in several respects a remarkable one. It constitutes the earliest record we possess of a really scientific investigation in the domain of biology based on systematic observation and experiment. Although written 270 years ago, the work is essentially modern in tone and method. It is, in fact, the precursor and prototype of the scientific "monograph" of our own day, and stands favourable comparison with the best master-pieces of recent times. In this treatise Harvey established absolutely the fact of the circulation of the blood, and the fact that the heart was the propulsive agent in the movement. But he was unable, from his want of a microscope, to indicate the precise path along which the blood travelled from the terminal arteries to the commencing veins. He erroneously conjectured that the blood percolated the organs and tissues as water percolates the earth and produces springs and rivulets. In less than two years after Harvey's death the improvements in the microscope enabled Malpighi and Leeuenhoek to demonstrate the completion of the circuit of the blood through the capillaries in the web of the frog's foot.

After the publication of his treatise on the circulation, Harvey seems to have concentrated himself, as regards physiological work, on his investigations concerning the generation of animals. He gradually accumulated an immense amount of information on this subject, which was eventually collected together and printed, towards the close of Harvey's life, in a separate volume, under the supervision of his friend Sir George Ent, with the title of "Exercitationes de Generatione Animalium." This book, though many times larger than the treatise on the motions of the heart and blood, is incomparably less satisfying. To the modern reader the reason of this shortcoming is plain enough; Harvey was stopped at every critical point by his want of a larger magnifying power. He had at his disposal only a pocket lens, which magnified perhaps four diameters. He knew nothing, and could know nothing, of the cellular elements of the ovum, nor of the motile filaments which constitute the essence of the spermatic fluid.

The later years of Harvey's life were passed in peaceful retirement. The civil troubles of the time had broken up his household and scattered his patients, but had left his private fortune unimpaired. At the age of sixty-eight he relinquished his appointments and practice, and went to reside with one or other of his brothers, who were wealthy London merchants. He still continued the studies he loved so well—for he had an enduring passion for original research—and maintained his interest in the College of Physicians, to which he was a large benefactor.

Sir George Ent gives us a touching glimpse of him as he appeared in his seventy-third year at the house of his brother Daniel, at Combe.

> "I found him, Democritus like, busy with the study of natural things, his countenance cheerful, his mind serene, embracing all within its sphere. I forthwith saluted him and asked if all were well with him? 'How can it,' said he, 'whilst the Commonwealth is full of distraction and I myself am still in the open sea? And truly did I not find solace in my studies and a balm for my spirit in the memory of my observations of former years, I should feel little desire for longer life. But so it has been, that this life of obscurity, this vacation from public business, which causes tedium and disgust to so many, has proved a sovereign remedy to me.'"

Harvey had the satisfaction of living to see his great discovery generally accepted as true. In his old age he was known and honoured throughout the learned world. The College of Physicians erected a statue in his honour. In his seventy-sixth year he was elected president of the College, but declined the honour on the plea of the infirmities of age. Harvey made a peaceful ending in his seventy-ninth year, and was buried in what is now called the "Harvey Chapel" in the parish church of Hempstead in Essex.

Mr. Power has produced a work of permanent value, which is not likely to be superseded. The book is invitingly got up, and is eminently readable. It should attract a large circle of readers both inside and outside the professional pale.

W. R.

THE NOTIONS OF CLASSICAL WRITERS ON GEOGRAPHY.

A History of Ancient Geography. By H. F. Tozer. Pp. xvii + 387. (Cambridge University Press, 1897.)

THE want of a short, popular history of classical geography is one which has been long felt, and there is no doubt that the little volume before us will help to fill it. The great work by the late Sir Henry Bunbury, from which Mr. Tozer has so largely drawn, is hardly fitted for a text-book, even for advanced students, for the subject of ancient geography is treated therein in such an exhaustive manner, that no ordinary student who has other subjects to master can ever hope to have sufficient time to study it in the way in which it should be studied. It is somewhat a matter of doubt if Mr. Tozer's, with its three hundred and seventy pages of closely-printed matter, is not too long when the absolute needs of the student are taken into consideration; still the reader will soon see how to pick out the important facts from this pleasantly written treatise, and how to let alone the generalisations and discussions of theories which though interesting enough are not essentials.

The first thing that strikes the reader is the fact that Mr. Tozer has described his work inaccurately; it is not a "History of Ancient Geography," but a "History of Ancient Classical Geography." In days gone by when Oriental studies had not attracted the attention of workers, and the works of Greek and Latin writers were believed to contain all the history of the nations that are past and gone, the title which Mr. Tozer has given to the work would have been well enough; in these days, however, it is misleading. On p. 3 Mr. Tozer says:

> "The natural starting-point for such a history must be the shores of the Mediterranean, because the peoples that dwelt in the neighbourhood of that sea first cultivated the science of geography on an extended scale, and it was from that quarter that the information was originally derived which furnished the material for such a study."
